Finally, the specific mechanisms operating in the interaction between host genetic factors and environment resulting in the induction of autoimmune disease of the heart is still not clear. In rheumatic fever there appears to be a marker called D8/17 which is inherited in an autosomal fashion and is preferentially increased in the B cells of rheumatic fever patients. However it is well-known that not all strains of group A streptococci cause rheumatic fever, even in the genetically susceptible individual. The most plausible explanation for this discrepancy is that only certain strains exhibit the epitopes that activate the immune system to produce tissue cross-reactive antibodies and activated T cells. Then, only in the context of the immune response (a heightened response, break in tolerance, etc.) will the disease occur. A similar mechanism can be postulated for the other cardiomyopathies, as it appears that only select individuals will develop progressive autoimmune disease following active infection. Future studies of each of the cardiopathies mentioned above should concentrate not only on the immune response of the host to a given cross-reactive antigen (either in the microbe or host) but should examine more carefully whether or not a particular microbe exhibits a specific epitope.

Obviously the field is ripe for applying the modern tools of molecular biology to the study of these intriguing host-microbial relationships in cardiac disease.

CARRIER

Huw Davies, Division of Life Sciences, King's College, London, UK

Our current understanding of antibody production by B lymphocytes, and the underlying cooperation between T and B lymphocytes, owes much to the early use of hapten-carrier conjugates in immunologic studies. It had been known from the work of Landsteiner and of Pauling in the 1940s that haptens, small antigenic determinants such as dinitrophenol (DNP), were insufficient by themselves to elicit specific antibody, but would bind to antibody once it was produced. The problem of how to generate hapten-specific antibodies was resolved by physical coupling of the hapten to a larger 'carrier' molecule. Proteins that have proved to be suitable carriers include bovine serum albumin, bovine gammaglobulin and ovalbumin.

We now understand that an efficient carrier is an immunogenic antigen that elicits a response from helper T lymphocytes. These cells will provide the necessary signals to enable B lymphocytes to generate hapten-specific antibodies. The following recapitulates the evidence for this. The first evidence that the carrier molecule itself was also recognized during an immune response to the hapten was provided by Ovary and Benacerraf in 1963. Animals primed with hapten A coupled to carrier B developed a secondary,

anamnestic antihapten (and anticarrier) antibody response after boosting with the original A–B conjugate. However, no antibodies to A were seen if the mice were challenged with hapten A coupled to an unrelated carrier such as carrier C. This curious phenomenon was termed the 'carrier effect'.

The mid-1960s was an exciting period that saw the emergence of the small circulating lymphocyte, hitherto regarded as uninteresting, as a primary component of the immune system. This apparently homogeneous population of cells was soon split into two functionally different, but cooperative subsets. The pioneering work of Gowans, in which the immune system could be severely compromised by depletion of circulating lymphocytes, demonstrated the fundamental importance of this cell. A functional dichotomy was revealed by extirpation experiments by both Glick and Cooper, using chickens, and in mice by Miller. Their findings, that depletion of B lymphocytes by bursectomy abolished antibody production without affecting cell-mediated immunity, and that depletion of T lymphocytes by neonatal thymectomy ablated both antibody and cellular immune responses, laid the foundations of modern cellular immunology. A series of influential studies then fol-

lowed (Claman; Davies; Mitchell and Miller) which dealt with establishing that an antibody response required both T and B lymphocyte subsets. In essence, B cells which were shown to be responsible for the generation of antibodies, and T cells which helped by providing regulatory signals, both had to interact with each other before a specific antibody response could be elicited.

The next problem was to explain how the antigen fitted into this interaction between helper T cells and B cells. Hapten-carrier conjugates provided a powerful tool in addressing this question. It was already known that some proteins were better carriers than others. Immunization with hapten-carrier conjugates only induced hapten-specific antibody responses when the carrier to which the hapten was attached was itself 'immunogenic', that is if the carrier was a T cell (or thymus) dependent antigen. Nonimmunogenic molecules served as poor carriers for haptens. This, and the 'carrier effect', indicated that separate recognition systems existed for the hapten and carrier, presumably mediated by B lymphocytes and T lymphocytes, respectively. The first direct evidence that cooperating T and B lymphocytes responded to different determinants on the same antigen molecule was provided by Mitchison (1971) using hapten-carrier conjugates. An adoptive transfer system, originally developed by Playfair and colleagues was used, in which lymphocytes were transferred from donor mice to a syngeneic recipient which had been rendered immunoincompetent by sublethal irradiation. T and B lymphocytes primed previously to different determinants were tested for their ability to cooperate within the recipient host (as manifested by the production of hapten-specific antibodies) in response to challenge with the determinants complexed on the same molecule. Mitchison observed that adoptively transferred spleen cells primed to hapten A conjugated to carrier B responded to challenge with A-B but not A-C (the carrier effect). However, if spleen cells from A-B primed mice were transferred together with cells primed to carrier C, an excellent response to challenge with A-C occurred. Moreover, hapten A and carrier C had to be physically linked.

These data, which have been confirmed in many experimental systems since, established that recognition of hapten and carrier is performed by different populations of cells that can cooperate to produce hapten-specific antibody, provided that the hapten and carrier are part of the same molecule. Formal proof that T lymphocytes recognized carrier determinants came from Raff in 1970. Employing the adoptive transfer system, depletion of Thy-1⁺ lymphocytes (T cells) from the carrier-primed population

using Thy-1-specific antibody plus complement abolished the adoptive antihapten response. Elimination of T lymphocytes from the hapten-primed population had no effect.

These experiments using defined B lymphocyte determinants coupled to carrier proteins revealed the importance of cognate T and B lymphocyte interactions in antibody synthesis and the recognition of spatially disparate determinants within the antigen by the cells participating in the response. A macromolecular antigen can thus be regarded as a complex of carrier and haptenic determinants, or, more precisely, T helper and B lymphocyte epitopes.

Recent interest in carriers has been revived by the potential use of synthetic polypeptides which contain antigenic determinants for use as vaccines. The efficient generation of antibody responses to peptides usually requires the peptide to be coupled to an immunogenic carrier as a source of helper T cell determinants. In order that an appropriate anamnestic response is mounted upon subsequent pathogenic infection, the carrier must possess helper T cell determinants derived from the same pathogen as those recognized by the antibodies, thereby ensuring that T and B cells capable of cognate interaction in response to the pathogen will be present in the memory pool. Studies in inbred animals have shown that the helper T cell determinants above, in the form of synthetic peptides, can be used in place of the carrier molecule - thereby raising the prospect of vaccines comprising no more than arrays of contiguous T and B cell epitopes.

CATALYTIC ANTIBODIES

Irene Lee and Stephen J Benkovic, Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania, USA

The concept of inducing antibodies that would possess, in addition to their exquisite ligand specificity, catalytic potential has its roots in the seminal contributions of Pauling. His proposal, that the ability of an enzyme to speed up a chemical reaction stemmed from the 'complementarity of the enzyme's active site structure to the activated complex', shifted the research focus from concerns about substrate–enzyme fit to a means for defining the structural requirements for binding the transition state. Since a transition state by definition has a negligible lifetime, evidence was sought for transition state stabilization in the tighter binding of inhibitors whose structures mimicked those of the presumed transition state relative to the weaker binding of substrate. Many examples of such high-affinity transition state inhibitors are now documented. However, stabilization of the transition state alone is necessary but not sufficient to give catalysis, which requires differential binding of substrate and transition state. The use of transition state analogs to induce catalytic antibodies successfully stems not only from this differential binding but other factors such as the introduction of catalytic residues. Nevertheless, it was apparent that such inhibitors would furnish a convenient starting point for creating catalytic antibodies which would owe their catalytic properties to their ability to bind the transition state of the reaction. Earlier attempts, however, were thwarted by the use of polyclonal rather than monoclonal antibodies, and by the need for better transition state mimics. In some cases, optimum haptens cannot be obtained owing to difficulties in the synthesis of precise mimics.

Reaction types catalyzed by antibodies

There are now approximately 100 reactions that have been catalyzed by antibodies. Representative examples include: pericyclic processes (Diels–Alder condensation, Claisen rearrangement, oxy-Cope rearrangement); elimination reactions (E2 elimination of benisoxazole, syn elimination of hydrogen fluoride from fluoroketones, dehydration, decarboxylation); various hydrolyses (carbonate esters, amides, esters, lactones, enol ethers); several types of bond-forming reactions (lactonization, peptide synthesis, cationic cyclization, aldol condensation) and redox processes (sulfide oxidation, reduction of ketones, epoxidation). Specific cases are given in Figures 1–

11. The chosen reactions illustrate the more significant features of antibody catalysis. The majority of antibody-catalyzed reactions are highly stereospecific; the Diels-Alder condensation (Figure 2) is an example of enantioselectivity in which the normally disfavored exo product is generated over the inherent

Figure 4 β -Elimination. (Reproduced with permission from Benkovic SJ. Catalytic antibodies. *Annual Review of Biochemistry* 61: 29-54, © 1992, by Annual Reviews Inc.)

Figure 5 Decarboxylation. (Reproduced with permission from Benkovic SJ. Catalytic antibodies. *Annual Review of Biochemistry* 61: 29-54, © 1992, by Annual Reviews Inc.)

endo specificity of the Diels-Alder reaction. Similarly the antibody catalyzed cyclization (Figure 7), in which racemic starting material is resolved kinetically, represents a case in which one major product is generated under solvolytic conditions that generally yield a mixture. The stereo- and regiospecificity of antibody catalysis, particularly for transformations for which there is no comparable enzymic process, has the potential to be useful in commercial synthetic and medical applications such as the formation of pharmaceuticals and prodrug activation.

For efficient catalysis, strategies are needed for the introduction of catalytic functions within the antibody-combining site correctly juxtaposed to the substrate. Charge complementarity to induce a catalytic base for promoting the elimination of hydrogen fluoride is shown in Figure 4. A catalytic base also is operative in the E2 elimination illustrated in Figure 3. The use of a reactive diketone hapten (Figure 11) to elicit antibodies with a combining-site amine provided catalysts capable of forming an active-site enamine. The latter forms an aldol product (the α -hydroxyketone) upon reaction with a substrate aldehyde followed by hydrolysis. Alternatively, the reactive reagent could be provided externally, as in the case of the periodate (Figure 10).

Nature of the combining site

There is a small repertoire of main-chain conformations, 'canonical structures', for at least five of the six hypervariable regions of antibodies whose

conformation is determined by a few key residues. The area of interaction between the antigen and antibody may be relatively flat and extensive for protein antigen binding to an antibody (700–750 Å²), whereas in the case of small organic molecules the binding may occur by way of clefts whose volumes

are in excess of $600\text{\AA}^3$. For small organic molecules the dissociation constant of the antibody-antigen complex ranges from 10^{-4} to 10^{-10} M, which if totally coupled to drive a chemical transformation would provide a free energy change up to 15 kcal M^{-1} , sufficient to promote most reactions in aqueous solution. The binding of antigen does not result in a global conformational change in the antibody. Rather, the union is accommodated by conformational adjustments in the specific amino acid side-chains that improve the initial binding interactions of hydrogen bonds, van der Waals and electrostatic forces. For a series of catalytic antibodies that were induced by phosphonate haptens (Figure 6) and hydrolyze esters, the active site structures are surprisingly congruent, suggesting the immunological response despite its diversity is tightly programmed by the chemical nature of the hapten. In general the crystallographic studies of catalytic antibodies show the bound hapten has induced antibodies that provide a three-dimensional arrangement of critical residues which resemble that found in enzymes of analogous activity. Although specific transition state binding is a feature of any enzyme or catalytic antibody, there is no assurance that the combining site has side residues suitable for efficient catalysis. From crystallographic studies of both the catalytic antibody and enzyme that catalyze the Claisen rearrangement of chorismate to prephenate, the active sites of both provide environments that complement the bound transition state analog (Figure 12). The 10^4 difference in catalytic efficiency may be more a matter of degree, as the enzyme apparently provides

more extensive electrostatic and hydrogen binding interactions than the antibody (Figure 12).

Nature of catalysis

Catalytic antibodies (abzymes) like enzymes process their substrates through a Michaelis complex in

which the chemical transformation occurs, followed by product dissociation. There are two general indices based on steady-state kinetic analyses that are used to assess the catalytic efficiency of an antibody: $k_{\text{cat}}/k_{\text{uncat}}$ and k_{cat}/K_M . The steady-state kinetics for all abzymes obey the Michaelis–Menten rate expression for both K_M (the concentration of sub-

Figure 11 (A) Mechanism-base screen for an active site lysine residue. (B) Antibody-catalyzed aldol condensation via Schiff-base formation. (Reproduced with permission from Jacobsen JR and Schultz PG (1995) The scope of Antibody Catalysis. *Current Opinion in Structural Biology* 5: 818–824.)

strate that produces one-half the maximal catalytic rate) and k_{cat} (the rate constant for product formation under conditions when the antibody is saturated with substrate). Note that the K_M parameter also represents an approximate measure for the dissociation of the abzyme–substrate complex. The meaning of the first index $k_{\text{cat}}/k_{\text{uncat}}$, where k_{uncat} is the rate constant for the same chemical process in

the absence of antibody, is obvious and for enzymes often exceeds 10^{10} . (For hydrolytic reactions both k_{cat} and k_{uncat} have the same units, as the activity of water is set equal to unity.) The second index of efficiency, the ratio k_{cat}/K_M , represents a measure of the kinetic barrier encountered, commencing with the combination of antibody and substrate and proceeding along the reaction coordinate to the trans-

ition state of the highest energy. This ratio has a limit of approximately $10^7 \text{ M}^{-1} \text{ s}^{-1}$ when the reaction is limited by diffusion together of the substrate and antibody.

The values of $k_{\text{cat}}/k_{\text{uncat}}$ for catalytic antibodies generally span a range from 10 to 10^6 . Likewise, the values of $k_{\text{cat}}/K_{\text{M}}$ are below that of a diffusion-controlled process. Both lines of evidence are consistent with the chemical step of a particular transformation as being rate limiting. For the majority of abzyme-catalyzed reactions there is a fair proportionality of the $k_{\text{cat}}/k_{\text{uncat}}$ ratio with the affinity of the antibody for its inducing hapten, although the coupling is generally not complete.

This observation is in accord with a view that antibodies catalyze their reactions primarily through restrictions which the active site cavity imposes on the translational and rotational movements of the bound substrate and to a lesser extent through active

site acid/base or nucleophilic catalysis. The latter apparently are not optimized like the situation with enzymes.

The few, unequivocal examples of covalent catalysis (in Figure 13 the reaction proceeds through an acyl histidine) rank near the upper end of the kinetic indices, although overall flux here may be limited by the buildup of product inhibition. The energy profile of this antibody-catalyzed reaction recapitulates a number of characteristics expected of an enzyme whose later evolution reduces the free energy barriers for the chemical and product release step. Therefore this catalytic antibody can be viewed as a primitive form of its enzyme counterpart. At present the success of this technology is greatly influenced by the serendipitous selection and placement of functional catalytic active site residues, particularly if the reaction is mechanistically complex.

Screening for catalysis

To date the majority of catalytic antibodies were derived from monoclonals, in most cases fewer than 100 were screened for activity. Recent developments include the adaptation of phage expression systems displaying single chain or Fab antibody fragments, permitting screening of larger numbers ($>10^6$) for catalytic activity. Given the often low activity of catalytic antibodies, several methods have been developed to identify an active fragment. Cat ELISA is based on screening for catalytic activity by using an amplification system in which the expected product is specifically bound by another antibody which recognizes the product as antigen. A second method depends on the catalytic release of a reactive species that can be trapped via covalent modification of bacteriophage-displayed antibody fragments, thus permitting the capture of the parent phage and the encoding DNA for the active abzyme. A third procedure is one of selection: antibodies that complement yeast or bacterial auxotrophs are identified by sustaining growth of the organism under minimal reaction conditions. The host organism, however, may also impose an addition selection on the catalytic antibody that can be recovered from an antibody library, as the host generally will not survive expressing an antibody with high toxicity. The latter two methods are particularly powerful because they reveal directly active species in large libraries. It is evident that screening large libraries resulting from primarily immunization or secondarily from a shuffled library of heavy and light chain fragments is the next critical step in the evolution of this technology for practical applications, which often require higher catalytic flux than generally found by limited screening.

environment and to execute effector functions. Therefore, a better knowledge and understanding of immune cell surface molecules has been a dream of immunologists since the formulation of Ehrlich's side-chain theory.

For several decades, however, progress in this field has been hampered by technical difficulties. The turning point was clearly the introduction of the monoclonal antibody (mAb)-producing hybridoma technology by George Köhler and César Milstein in 1975. This technique allowed workers for the first time to reproducibly demonstrate, purify and characterize minute amounts of distinct molecules on the surface of immune cells, the leukocytes, by specific mAbs.

The introduction of this technology into leukocyte biology quickly led to the identification of a vast array of single mAb-defined, but otherwise ill-characterized cell surface molecules by individual laboratories. In 1981, at the leukemia marker conference held in Vienna many of these new mAb-defined molecules were presented and discussed. There it became clear that intense international collaboration and gathering of the expertise available in the various laboratories is a prerequisite for optimal progress in this field.

Laurence Boumsell and Alain Bernard were the pioneers to initiate this international collaboration and to gather a group of scientists (J. Dausset, R.L. Evans, J.A. Hansen, B.F. Haynes, W. Knapp, A.J. McMichael, C. Milstein, E.L. Reinherz, S.F. Schlossman) willing to collaborate in this approach. The still valid basic rules of this cooperation were set up by this council, and Laurence Boumsell and Alain Bernard then organized in 1981/82 the First International Workshop on Human Leukocyte Differentiation Antigens with the final conference being held in Paris in 1982. Everybody working in the field was invited to join and to submit mAbs for evaluation and/or to offer analytical skills for characterizing these mAbs.

The specific reactivity of an mAb with certain cell types and/or differentiation stages and the molecular weight of the recognized antigen (molecule) were at that time the main features which allowed distinction of different and clustering of similar mAb specificity. This explains the now historical terms used in the nomenclature (CD for cluster of differentiation) and in the title of the workshop and conference series (Leukocyte Differentiation Antigens rather than Leukocyte Surface Molecules).

So far, six international workshops and conferences have been held. Each workshop collects data over a period of approximately 2 years and meets in a conference which results in a well-documented proceedings volume: Ist Conference – Paris November 1982, IInd Conference – Boston September 1984, IIIrd Conference – Oxford September 1986, IVth Conference – Vienna February 1989, Vth Conference – Boston November 1993, VIth Conference –

Kobe November 1996. The organization of the VIIth Workshop is led by David Mason (Oxford), and the Conference is planned for June 2000 in Harrogate, UK, <http://phoenix.jr2.ox.ac.uk/HLDA7>

The principal organization of the workshops has not changed dramatically since the Ist Workshop in Paris. However, new technologies have been integrated into the evaluation process rapidly, and have profoundly influenced the overall design and philosophy of the series. This has not only maintained the nomenclature authority of the workshop series but also strengthened its role as a creative international instrument with a substantial impact on modern immunological research.

In essence, international investigators are invited to submit interesting mAbs to the workshop organizers, who group the mAbs in coded or open panels on the basis of the information provided. The panels are then distributed to investigators who can offer informative and innovative studies on these reagents. The generated data have to be returned to the organizers who are responsible for joint evaluation and publication. For example, at the VIth Workshop, within 2 years, 1152 mAbs directed to more than 200 leukocyte cell surface molecules were evaluated by more than 500 laboratories. This resulted in 42 new CD entities, the redefinition of several previously established, mainly provisional clusters, and a considerable advancement in understanding the structure and function of leukocyte surface molecules in general. The database of the VIth Workshop including the individual reaction patterns of the mAbs is available at the Internet address: <http://immunol.mcb.osaka-u.ac.jp/>.

Originally and still as a rule, the CD designation describes a cluster of mAbs (e.g. CD2 mAbs) all of which show identical cellular reaction patterns and identify the same molecular species. Consequently, the term 'anti-CD...' would mean anti-idiotypes and, therefore, should not be used to name CD mAbs. Later, the CD designation was used to describe the recognized molecule, but it had to be clarified by using the terms antigen or molecule (e.g. CD2 molecule). Meanwhile, the CD nomenclature without the additive is used by most people to designate the leukocyte surface molecules, the characterization for which the CD mAbs have been established.

So far, 202 CD entities have been assigned to the 166 main CDs delineated in Table 1. Provisional clusters are designated as CDw. Further information on the CDs is available in the proceedings of the individual workshops and the Protein Reviews on the Web (PROW) database. PROW has been established based on a concept developed by Stephen Shaw and aims to organize and synthesize information on all

Table 1 Human leukocyte CD molecules

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD1a	T6	Thy, LHC, DC	Noncovalently associated with β_2 M. Structural similarity with MHC-class I molecules (see CD1b and CD1c)	49
CD1b		Thy, DC	Noncovalently associated with β_2 M (see also CD1a). Potential lipid antigen-presenting molecule	45
CD1c		Thy, LHC, DC, B sub	Noncovalently associated with β_2 M (see also CD1a). Potential lipid antigen-presenting molecule	43
CD2	T11; Tp50; sheep red blood cell (SRBC) receptor; LFA-2	T, NK	Cytoadhesion molecule binding to CD58 molecule (LFA-3), CD48 molecule and probably also to CD59 molecule	50
CD2R	CD2 epitopes restricted to activated T cells	T act	Same molecule as CD2 molecule, CD2R antibodies recognize CD2 epitopes expressed on activated T cells	50
CD3	CD3 complex	T	Multigene cell surface complex that is part of the T cell antigen receptor	16, 20, 22, 25, 28
CD4	T4	T sub	Coreceptor of the T cell antigen receptor; binds to MHC class II molecules. Also, receptor for interleukin 16, and for human immunodeficiency virus	55–59
CD5	Tp67	T, B sub	Member of the scavenger receptor family (see CD6). Possible CD72 counter-receptor	67
CD6	T12	T, B sub	Member of the scavenger receptor family. Counter-receptor of CD166	110
CD7		T sub	Type I integral membrane glycoprotein	40
CD8	T8	T sub	Two-chain complex expressed as disulfide-linked α/α homodimers or α/β (see CD8beta) heterodimers. Coreceptor of the T cell antigen receptor; binds to MHC class I molecules	32–38
CD8beta	T8	T sub	β chain of CD8	30–34
CD9	p24	Pre-B, T act, Plt, Eo, EC	Member of the tetraspans gene molecules that contain four transmembrane domains and have both the N- and C-termini on the cytoplasmic side (see CD37, CD53, CD63, CD81, CD82, CD151)	24
CD10	Neutral endopeptidase; gp100; common acute lymphatic leukemia antigen (CALLA)	Lymphoid Prog, cALL, Germ Ctr. B, G	Type II transmembrane glycoprotein, which is a neutral endopeptidase (enkephalinase)	100
CD11a	α chain of: leukocyte function associated antigen 1 (LFA-1), gp180/95	Leukocytes broad	β_2 -integrin member (see CD11b, CD11c, CD18). The CD11a/CD18 (LFA-1) complex has binding capacity to CD54 molecules (ICAM-1), CD102 molecules (ICAM-2), CD50 molecules (ICAM-3), Laisolsteiner-Wiener antigen (ICAM-4), telencephalin (ICAM-5)	180
CD11b	α chain of: C3bi receptor, complement receptor type 3 (CR3), gp155/95, Mac-1, Mo1	M, G, NK, T sub	β_2 -integrin member (see CD11a, CD11c, CD18). The CD11b/CD18 complex (CR3) binds C3bi, lipid IVa in LPS, kininogen, coagulation factor X, CD54 molecules, the neutrophil inhibition factor of the hookworm <i>Ancylostoma caninum</i> , oligonucleotides	170
CD11c	α chain of: complement receptor type 4 (CR4); gp150/95	M, G, NK, B sub, T sub	β_2 -integrin member (see CD11a, CD11b, CD18). The CD11c/CD18 complex (CR4) binds C3bi, fibrinogen and CD54 molecules	150
CDw12		M, G, Plt		90–120
CD13	Aminopeptidase N; gp150;	M, G	Type II transmembrane glycoprotein, identical to the proteolytic enzyme aminopeptidase N	150

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD14	gp55; lipopolysaccharide (LPS) receptor	M, G	Receptor for the LPS/LPS binding protein (LBP) complex	55
CD15	Lewis ^x (Le ^x); 3-fucosyl-N-acetyllactosamine (3-FAL); X-Hapten; lacto-N-fucopentaose III; SSEA	G, some antibodies also M	CD15 antibodies recognize the trisaccharide 3-FAL (Gal1-4 (Fuc1-3) GlcNAc) which is also recognized by CD62P molecules	shared by a variety of proteins and lipids
CD15s	Sialyl Lewis ^x (sLe ^x)	Broad	Sialylated form of CD15. It is recognized by CD62E, CD62L and CD62P molecules	shared by a variety of proteins and lipids
CD16	Fc γ receptor type IIIa (Fc γ RIIIa); gp50-65	NK, G, Mac	Low-affinity receptor for complexed IgG	50-65
CD16b	Fc γ receptor type IIIb (Fc γ RIIIb);	G	Glycosylphosphatidylinositol-anchored form of the CD16 molecule expressed on granulocytes	48-60
CDw17	Lactosylceramide	G, M, Plt	Lactosylceramide (Gal-Glc-Cer type 2 chain)	
CD18	Integrin β_2 β chain	Leukocytes broad	Noncovalently linked to either CD11a, CD11b or CD11c molecules (α chains) Defect in CD18 results in leukocyte adhesion deficiency (LAD)	95
CD19	Bgp95, B4	B	Part of the B cell antigen receptor complex	95
CD20	B1; Bgp35	B	Phosphoprotein expressed on B cells in three forms (37 and 35 and 33 kDa) as a result of different phosphorylation. This molecule has four membrane-spanning regions	33, 35, 37
CD21	C3d receptor (CR2); gp140	B sub	Member of the regulator of complement activation (RCA) gene family (see CD35, CD46, CD55). Molecule functions as C3d receptor (CR2) and serves also as receptor for Epstein-Barr virus	140
CD22	Bgp135; BL-CAM	Cytoplasm: pan B; surface: B sub	Functions as an adhesion molecule with a sialic acid binding capacity for carbohydrates which were found e.g. on CD45RO, CDw75 and CDw76 molecules	135, 140
CD23	Low-affinity Fc ϵ -receptor; Fc ϵ RII; gp50-45; Blast-2	B, M	The extracellular region contains a C-type lectin domain (see CD69, CD72, CD94, CD161)	45-50
CD24	Heat stable antigen homolog; BA-1	B, G, EPC	Glycophosphoinositol-linked, extremely glycosylated protein. Possible counter-receptor for CD62P	42
CD25	Interleukin (IL)-2 receptor α chain; Tac-antigen	T act, B act, M act	Has low-affinity IL-2 binding capacity. By noncovalently associating with the CDw122 molecule and the CD132 (common to CD124 and CD127) molecule, it forms the high-affinity IL-2 receptor complex	60
CD26	Dipeptidylpeptidase IV; gp120; Ta1	T act, B, Mac, NK	Has also collagen binding properties. Associated with adenosine deaminase and CD45 molecules	110
CD27	T14	T sub	Member of the tumor necrosis factor (TNF)/nerve growth factor (NGF) receptor family (see CD30, CD40, CD95, CD120a, CD120b, CD134, CDw137). Counter-receptor for CD70	55
CD28	Tp44;	T sub	Counterreceptor for CD80, CD86 and B7-3 molecules	44
CD29	Integrin β_1 chain; platelet GPIIa; VLA (CD49) β chain	Broad	β chain of the VLA protein family (CD49 molecule family), however, can also associate with other integrin α chains (see CD51)	130
CD30	Ki-1 antigen	T act, B act, Reed Sternberg cells, Hodgkin cells	Member of the TNF/NGF receptor family (see CD27, CD40, CD95, CD120a, CD120b, CD134, CDw137). Counter-receptor for CD153	105

Table 1 Continued

	Other name (s)	Main reactivity of mAbs	Short characteristic of the CD molecule	Molecular weight reduced (kDa)
CD31	PECAM-1; platelet GPIIa ¹ ; endocam	Plt, M, G, B, T sub	Adhesion molecule involved in migration of leukocytes and regulation of the T cell response	140
CD32	Fc γ receptor type II (Fc γ RII), gp40	M, G, B, Eo	Six isoforms are known which originate from alternative splicing of three genes on chromosome 1 (Fc γ RIIA, -B and -C)	40
CD33	My9	M, normal and malignant myeloid progenitor cells	Related to myelin-associated glycoprotein and CD22 molecules	67
CD34	My10	Prog, EC	Sialomucin-like (see CD43, CD68, CD164) transmembrane glycoprophosphoprotein. Potential cytoadhesion molecule probably interacting with CD62E and CD62L molecules	105–120
CD35	C3b/C4b receptor; complement receptor type 1 (CR1)	G, M, B, some T/NK	Has binding capacity for C3b, iC3b, C3c and C4b complement fragments. Mediates erythrocyte clearance of immune complexes, involved in inhibition of complement activation by blocking C3 convertase formation	190, 220, 250, 280
CD36	Platelet GPIV, GPIIb, OKM-5 antigen	M, Plt, (B)	Functions as receptor for <i>Plasmodium falciparum</i> -infected erythrocytes. Binding affinity for thrombospondin (thrombospondin receptor), collagen I and IV and oxidized low-density lipoprotein has been shown	90
CD37	gp40-52	B, (T), (M), (G)	Member of the tetraspans family (see CD9)	36–52
CD38	T10; gp45	PC, Thy, T act	Has NAD ⁺ glycohydrolase, ADP ribosylcyclase and cyclic ADP-ribose hydrolase activity	45
CD39	gp80	B sub		80
CD40		B, DC	Member of the TNF/NGF receptor family (see CD27, CD30, CD95, CD120a, CD120b, CD134, CDw137). Counter-receptor of CD154	44, 48
CD41	Platelet glycoprotein GPIIb	Plt	Heterodimeric 140 kDa transmembrane glycoprotein (posttranslationally cleaved into a disulfide linked 120 kDa α chain and a 22 kDa β chain) also known as platelet glycoprotein GPIIb, which forms a calcium-dependent complex with platelet glycoprotein GPIIIa (CD61 molecule)	120, 22 (GPIIb), 110 (GPIIIa)
CD42a	Platelet glycoprotein GPIX	Plt	Forms a noncovalent complex (CD42 complex) with platelet glycoprotein GPIb and GPV (see CD42b, CD42c and CD42d). Complex functions as receptor for von Willebrand factor and as von Willebrand factor-dependent adhesion receptor	23
CD42b	Platelet glycoprotein GPIb- α	Plt	135 kDa protein (α chain) that forms with the CD42c molecule (β chain) a disulfide-linked 160 kDa membrane protein known as platelet glycoprotein GPIb (subunit of the CD42 complex, see CD42a)	135(α), 22(β)
CD42c	Platelet glycoprotein GPIb- β	Plt	See CD42b	135(α), 22(β)
CD42d	Platelet glycoprotein GPV	Plt	See CD42a	85
CD43	Leukosialin; gp95; sialophorin; leukocyte sialoglycoprotein; gp115	T, G, M, NK, Plt	Member of the 'cell surface mucin' family (see CD34, CD68, CD164). Suggested to function as adhesion molecule interacting with MHC class I, CD54 and CD62P molecules, or (controversial) as antiadhesion protein	95–135

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD44	Pgp-1; gp80-95; In (Lu)-related p80, Hermes antigen, ECMR-III and HUTCH-I	T, B, G, M	Receptor for hyaluronate and involved in lymphocyte homing	80–95
CD44R	CD44 variant; CD44v9	T act, carcinoma cells	CD44R (CD44v9) may be a marker for cell transformation	130, 190, 250, 300
CD45	T200; leukocyte common antigen (LCA); EC3.1.3.4	Leukocytes	Transmembrane glycoprotein consisting of 4 isoforms, which result from differential splicing. The CD45 molecule has intrinsic cytoplasmic protein tyrosine phosphatase activity	220, 205, 190, 180
CD45R0	Restricted T200; gp180	T sub, G, M	Isoform of the CD45 molecule family, this isoform does not contain exon A, B, or C sequences. Interacts via carbohydrate residues with the CD22 molecule	180
CD45RA	Restricted T200; gp220; isoform of leukocyte common antigen	T sub, B, G sub, M	Isoform determinant of CD45 sharing exon A sequences. Expressed on resting/naive T cells	220
CD45RB	Restricted T200; isoform of leukocyte common antigen	T sub, B, G, M	Isoform determinant of CD45 sharing exon B sequences	220, 205, 190
CD45RC	Restricted T200; isoform of leukocyte common antigen	T sub, B, NK	Isoform determinant of CD45 sharing exon C sequences within CD4 cells expressed on long living memory cells	220, 205
CD46	Membrane cofactor protein (MCP); gp45-70	Leukocytes broad	Member of the RCA gene family (see CD21, CD35, CD55). Inhibits complement activation by inhibition of C3 convertase formation. Receptor for measles virus	51–58/59–68
CD47	Integrin associated protein; OA3; 1D8	Extremely broad	Physically and functionally associated with the vitronectin receptor (CD51/CD61)	47–52
CD48	gp41; BLAST-1	Leukocytes	Glycophosphatidylinositol-linked glycoprotein. Counter-receptor for CD2	41
CD49a	VLA-1 α chain	T cultured	Associates with the CD29 molecule to form the VLA-1 (integrin $\alpha_1\beta_1$) complex. VLA-1 mediates cell adhesion to collagens and laminin	210
CD49b	VLA-2 α chain platelet glycoprotein GPIa	Plt, T cultured	Associates with CD29 molecules to form the VLA-2 (integrin $\alpha_2\beta_1$) complex. Functions as collagen receptor or collagen/laminin receptor, receptor for echovirus 1	170
CD49c	VLA-3 α chain	Adherent cell lines	Associates with CD29 molecule to form the VLA-3 (integrin $\alpha_3\beta_1$) complex. VLA-3 mediates cell adhesion to fibrinogen, laminin, collagens and epiligrin/kalinin, VLA-2	125, 30
CD49d	VLA-4 α chain	M, T, B, (LHC), Thy	Associates with CD29 molecules in VLA-4 (integrin $\alpha_4\beta_1$) which binds fibronectin, thrombospondin, invasin and CD106 molecules. Upon noncovalent association with the integrin β_7 subunit the integrin $\alpha_4\beta_7$ complex is formed, which binds fibronectin, MadCAM and CD106 molecules	150
CD49e	VLA-5 α chain	T, M, Plt	Associates with CD29 molecules to form the VLA-5 (integrin $\alpha_5\beta_1$) complex, which is a receptor for fibronectin	135, 25
CD49f	VLA-6 α chain	Plt (T)	Associates with CD29 molecules in VLA-6 (integrin $\alpha_6\beta_1$). This complex has been shown to be a laminin receptor. The CD49f molecule can also associate with CD104 molecules to form the $\alpha_6\beta_4$ laminin receptor	120, 130
CD50	Intercellular adhesion molecule 3 (ICAM-3)	Broad, not on EC	Functions as counter-receptor for LFA-1 (CD11a/CD18)	130

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD51	Vitronectin receptor (VNR) α chain; integrin α_v	(Plt), EC, Fibroblasts	Can noncovalently associate with β_1 (CD29), β_3 (CD61), β_5 , β_6 or β_8 integrins. The $\alpha_v\beta_1$ complex was found to bind vitronectin, fibronectin and collagen I. The $\alpha_v\beta_3$ complex binds vitronectin, fibronectin, fibrinogen, von Willebrand factor, thrombospondin, osteopontin and collagen, $\alpha_v\beta_5$ binds to vitronectin, and $\alpha_v\beta_6$ to fibronectin	125, 25
CD52	Campath-1; gp21–28	Leukocytes	Good target for complement-mediated cell lysis	21–28
CD53		Exclusively leukocytes	Member of the tetraspans family (see CD9)	32–40
CD54	Intercellular adhesion molecule 1 (ICAM-1)	Broad	Counter-receptor of LFA-1 (CD11a/CD18) and CR3 (CD11b/CD18). Also serves as major group rhinovirus receptor	90
CD55	Decay-accelerating factor (DAF)	Broad	Glycophosphatidylinositol-linked membrane glycoprotein. Molecule prevents the formation and causes dissociation of C4b2a and C3bBb, the amplification convertases of the complement cascade. Counter-receptor of the CD97 molecule, receptor for echoviruses and enterovirus	80
CD56	NKH1; isoform of neuronal cell adhesion molecule (N-CAM)	NK, T act	Homotypic adhesion molecule	175–185
CD57	HNK1; gp110	NK, T, B sub, brain	Carbohydrate structure, probably attached to several proteins and lipids	
CD58	Leukocyte function-associated antigen 3 (LFA-3)	Leukocytes, EC, EPC, fibroblasts	Counterreceptor of CD2	40–65
CD59	gp18-20; Ly6 analogous; homologous restriction factor 20 (HRF-20); Protectin	Broad	Glycophosphatidylinositol-linked glycoprotein. Mediates inhibition of the complement membrane attack complex by binding to C8 on C5b678 and thereby preventing accumulated binding of C9	18–20
CDw60		T sub, Plt	Acetylated disialosyl group (NeuAc-NeuAc-Gal) predominantly found on ganglioside GD3	
CD61	Integrin β_3 chain, platelet glycoprotein GPIIIa	Plt	Forms a complex with CD41. The CD61 molecule can also associate with integrin α_v (CD51 molecule) forming the $\alpha_v\beta_3$ vitronectin receptor	90
CD62E	E-selectin; ELAM-1; LECAM-2	EC act	Related to CD62L and CD62P molecules (selectin family). Recognizes carbohydrate ligands (e.g. CD15s) on various molecules including GlyCAM1, CD34, CD162, ESL1	115
CD62L	L-selectin; LAM-1; Leu-8; TQ1; LECAM-1	G, M, T, B sub, NK	Recognizes carbohydrate ligands (e.g. CD15s) on various molecules including GlyCAM-1, MadCAM, CD162, CD34 as well as sulfated glycolipids	75
CD62P	P-selectin; gmp140; PADGEM	Plt act, EC act	Recognizes carbohydrate ligands (e.g. CD15 and CD15s) on various molecules including CD162	150
CD63	Platelet 53 kDa activation antigen; LIMP; ME491	Plt act, M, (G, T, B)	Member of the tetraspans family (see CD9)	30–60
CD64	Fc γ receptor type I (Fc γ RI); high-affinity Fc-IgG receptor	M, G act	Encoded by three genes. Associates with the γ chain of Fc ϵ receptor type I	75

Table 1 Continued

	Other name (s)	Main reactivity of mAbs	Short characteristic of the CD molecule	Molecular weight reduced (kDa)
CD65	Desialylated form of CD65s	G	Fucoganglioside (Gal-GlcNAc-Gal-GlcNAc(Fuc)-Gal-Gl cNAc-Gal-GlcNAc-Gal-Glc-Cer) based on a type II chain. Desialylated form of CD65	
CD65s	Ceramide-dodecasaccharide 4c, VIM2 Antigen	M, G, AML blasts	Fucoganglioside (NeuAc-Gal-GlcNAc-Gal-GlcNAc(Fuc)-Gal-Gl cNAc-Gal-GlcNAc-Gal-Glc-Cer). Carried by various glycolipids and glycoproteins. Potential ligand for CD62E and CD62L	
CD66a	Biliary glycoprotein (BGP); nonspecific cross-reacting antigen (NCA) 160	G, EPC	Member of the carcinoembryonic antigen (CEA) gene family. Adhesion molecule, has bacterial binding property, in particular, for Opa-proteins of pathogenic <i>Neisseria</i>	160–180
CD66abce		G	Antibodies recognizing CD66a, CD66b, CD66c, CD66e molecules	
CD66acd		G	Antibodies recognizing CD66a, CD66c, CD66d molecules	
CD66acde		G	Antibodies recognizing CD66a, CD66c, CD66d, CD66e molecules	
CD66ace		G	Antibodies recognizing CD66a, CD66c, CD66e molecules	
CD66ade		G	Antibodies recognizing CD66a, CD66d, CD66e molecules	
CD66ae		G	Antibodies recognizing CD66a, CD66e molecules	
CD66b	CD67; p100; CGM6; nonspecific cross-reacting antigen (NCA) 95	G	Glycophosphatidylinositol-anchored glycoprotein. Member of the carcinoembryonic antigen (CEA) gene family. Adhesion molecule	95–100
CD66be		G	Antibodies recognizing CD66b, CD66e molecules	
CD66c	nonspecific cross-reacting antigen (NCA) 50, NCA 90 or TEX	G	Glycophosphatidylinositol-anchored glycoprotein. Member of the carcinoembryonic antigen (CEA) gene family. Recognizes type 1 fimbriae from <i>E. coli</i> and Opa-proteins of pathogenic <i>Neisseria</i>	90–95
CD66ce		G	Antibodies recognizing CD66c, CD66e molecules	
CD66d	CGM1	G	Member of the carcinoembryonic antigen (CEA) gene family. Recognizes Opa-proteins of pathogenic <i>Neisseria</i>	30
CD66de		G	Antibodies recognizing CD66d, CD66e molecules	
CD66e	Carcinoembryonic antigen (CEA)	EPC	Prototype of the carcinoembryonic antigen (CEA) gene family. Glycophosphatidylinositol-anchored. Adhesion molecule, binds to CD66a and CD66c molecules and Opa-proteins of pathogenic <i>Neisseria</i>	180–200
CD66f	Pregnancy-specific glycoprotein (PSG), SP-1	Myeloid cells, placenta, fetal liver	Secreted molecule. Member of the carcinoembryonic antigen (CEA) gene family. Low blood level predicts spontaneous abortion	54–72
CD67	Deleted, now CD66b			
CD68	gp110, Macrosialin	M, Mac	Mucin-like molecule (other members CD34, CD43, CD164, GlyCAM-1) and lysosomal/plasma membrane shuttling protein (see CD107a, CD107b). Recognizes oxidized low-density lipoprotein	110
CD69	Activation inducer molecule (AIM); EA1; MLR; Leu23; BL-AC/p26	B and T early act, Mac act	Member of the Ca ²⁺ -dependent (C-type) lectin superfamily of type II transmembrane receptors (see CD23, CD72, CD94, CD161)	28, 34
CD70	Ki-24	T, B-EBV, pre-BLL act	Member of the TNF family (see CD153, CD154, CD95L). Counter-receptor for CD27	50
CD71	Transferrin receptor; T9 antigen	T and B act, Mac, proliferating cells	Mediates cellular iron uptake via internalization and recycling of transferrin	95

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD72	Lyb-2	B	Member of the Ca ²⁺ -dependent (C-type) lectin superfamily of type II transmembrane receptors (see CD23, CD69, CD94, CD161). Possible counter-receptor for the CD5 molecule	39, 43
CD73	ecto-5'-nucleotidase (ecto-5'-NT), EC.3.1.3.5.	B sub, T sub, EC	Glycophosphatidylinositol-linked membrane glycoprotein. Catalyses the dephosphorylation of purine and pyrimidine ribo- and deoxyribonucleoside	69
CD74	MHC class II-associated invariant chain (Ii)	B, M, T act, EC act, EPC act	Involved in intracellular transport and surface expression of MHC class II proteins	33, 35, 41, 42
CDw75		Mature B	Carbohydrate, suggested to be recognized by CD22 molecules	
CDw76		B, T sub, EC	Carbohydrate of the sialylated type 2 glycosphingolipids. May be recognized by CD22 molecules	
CD77	Globotriaosylceramide (Gb3); P ^k blood group antigen; Burkitts lymphoma-associated antigen (BLA), ceramide trihexoside (CTH)	B sub	Neutral glycosphingolipid of the globo series (Gal α 1-4 Gal β 1-4 Glc1-1 Cer). Interacts with CD19 molecules on B cells and seems to be involved in CD19 signaling	
CDw78	Ba	B	Not fully characterized	
CD79a	mb-1; Ig α	B	Forms with the CD79b molecule a disulfide-linked heterodimer which functions as a coupling module of the B cell antigen receptor	47
CD79b	B29; Ig β	B	Forms with the CD79a molecule a disulfide-linked heterodimer which functions as a coupling module of the B cell antigen receptor	37
CD80	B7-1; BB1	B, B act, M, DC, T act	Counter-receptor of the T cell accessory molecules CD28 and CD152	60
CD81	Target of an antiproliferative antibody (TAPA-1); M38	Broad	Member of the tetraspans family (see CD9)	26
CD82	R2; 4F9; C33; IA4	M, B, B act, T act, LGL	Member of the tetraspans family (see CD9)	40-60
CD83	HB15	LHC, DC, reticulum cells (T and B act)	Dendritic cell marker	45
CD84	p75	B, M, Plt, Mac.	Not fully characterized	74
CD85	VMP-55; GH1/75	PC, Mac, hairy cells	Not fully characterized	83
CD86	B7-2; B70	B act, M, DC	Structurally related to the CD80 molecule, and functions as counter-receptor for the T cell accessory molecules CD28 and CD152	75
CD87	Urokinase plasminogen activator-receptor (uPA-R)	M, G, EC	Glycophosphatidylinositol-anchored glycoprotein involved in cell migration. Serves also as receptor for vitronectin	45-55
CD88	C5 α receptor	G, M, DC, smooth muscle cells	Member of the rhodopsin superfamily that contain seven transmembrane domains	
CD89	Fc α receptor	G, M, B sub, T sub	Binds serum and secretory IgA1 or IgA2	55-70
CD90	Thy-1	Prog sub, EC, neurons	Glycophosphatidylinositol-anchored protein	25-35
CD91	α_2 -macroglobulin receptor; low-density lipoprotein receptor-related protein	M	Receptor for a variety of ligands including α_2 -macroglobulin-proteinase complex, plasminogen activators (urokinase and tissue) in complex with type 1 inhibitors, chylomicron remnants, lipoprotein lipase, <i>Pseudomonas</i> exotoxin A	85, 515
CDw92	p70	G, M		70

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD93	p120	M, EC		120
CD94		NK, T sub	Member of the Ca^{2+} -dependent (C-type) lectin superfamily of type II transmembrane receptors (see CD23, CD69, CD72, CD161). The CD94 molecule forms a disulfide linked heterodimer with NKG2A. This complex functions as receptor for certain HLA-A, B, C alleles and HLA-G, and is involved in the downregulation of NK cell activity. In contrary, upon interaction with a less-defined 39 kDa protein, CD94 seems to form an activatory NK cell receptor	30
CD95	Apo-1; Fas	T act, M act, B act	Member of the TNF/NGF receptor family (see CD27, CD30, CD40, CD120a, CD120b, CD134, CDw137)	43
CD96	Tactile	T, T act		160
CD97	p74/80/89	G, M, T act, B act	Seven-span transmembrane protein belonging to the secretin receptor superfamily. Counter-receptor for the CD55 molecule	74, 80, 89
CD98	4F2	T, B, Plt	Disulfide-linked heterodimer	40, 80
CD99	E2; MIC2	Broad	The extracellular domain contains five G-X-Y repeats that are found in collagen and collagen-like proteins	32
CD99R	Restricted CD99	T sub	CD99 epitopes, the expression of which is restricted to T cell subpopulations	
CD100	p150	Broad	The extracellular region consists of a semaphorin domain and an Ig-like domain. Modifies CD40-CD40L B cell signaling by augmenting B cell aggregation and survival	150
CD101	P140; V7	G, M, T sub, DC	The extracellular domain consists of 7 IgV-like domains. Some mAb modify T cell activation	140
CD102	Intercellular adhesion molecule 2 (ICAM-2)	M, Plt	Functions as counter-receptor for the CD11a/CD18 (LFA-1) complex	55–65
CD103	α chain of HML-1, $\alpha_E\beta_7$ integrin; integrin α_E	Intestinal intraepithelial lymphocytes, hairy cells	Post-translationally cleaved into two disulfide-linked units of 25 kDa and 150 kDa. Noncovalently associates with the 105 kDa integrin β_7 chain to form the human mucosal lymphocyte 1 (HML-1) antigen	25, 150
CD104	Integrin β_4 chain		Associates with CD49f molecule (integrin α_6 chain) to form the integrin $\alpha_6\beta_4$ laminin receptor. This complex also binds epiligrin	220
CD105	Endoglin	EC, M act	Binds in association with TGF β receptor I and II, TGF β_1 , and TGF β_3	95
CD106	Vascular cell adhesion molecule 1 (VCAM-1); INCAM110	EC act	Binds to CD49d/CD29 (VLA-4, integrin $\alpha_4\beta_1$) and CD49d/integrin β_7 (integrin $\alpha_4\beta_7$) complexes	95, 100
CD107a	Lysosomal-associated membrane protein (LAMP)-1	Plt act, EC act, G act	Together with the 60% homologs CD107b molecule, the major sialoglycoprotein of lysosomal membranes	110
CD107b	Lysosomal-associated membrane protein (LAMP)-2	Plt act, EC act, G act	Together with the 60% homologous CD107a molecule, the major sialoglycoprotein of lysosomal membranes	120
CDw108	GPI-gp80, JMH blood group antigen	HPB-ALL (T cell line)	Glycosylphosphatidylinositol-anchored cell membrane glycoprotein	75
CD109		EC, T act, Plt, stromal cells	Glycosylphosphatidylinositol-anchored cell membrane glycoprotein. Sialomucin	120–165, 170
CD114	G-CSF receptor	G, M	Member of the cytokine receptor family	130

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD115	Colony-stimulating factor (CSF)-1 receptor; macrophage CSF receptor, <i>c-fms</i> proto-oncogene	M, Mac	Belongs to the Ig and receptor tyrosine kinase family (see CD117, CD135, CD140a, CD140b). The cytoplasmic region contains a protein tyrosine kinase domain	150
CD116	Granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor α chain	M, G	Member of the cytokine receptor (hematopoietin) superfamily. Upon association with CDw131 (common to CDw123 and CDw125), it forms the high-affinity GM-CSF receptor	75–85
CD117	Stem cell factor receptor; steel factor receptor; <i>c-kit</i>	Mast cells, myeloid Prog	Belongs to the Ig and receptor tyrosine kinase family (see CD115, CD135, CD140a, CD140b)	145
CDw119	Interferon γ receptor	M, G	Related to the interferon α/β receptor and the CD142 molecule	90–100
CD120a	55 kDa tumor necrosis factor receptor	(M)	Member of the TNF/NGF receptor family (see CD27, CD30, CD40, CD95, CD120b, CD134, CDw137). It binds both TNF α and β with high affinity	50–60
CD120b	75 kDa tumor necrosis factor receptor	M, G	Member of the TNF/NGF receptor family (see CD27, CD30, CD40, CD95, CD120a, CD134, CDw137). It binds both TNF α and β with high affinity	75–85
CD121a	Interleukin 1 receptor type I	T, B, M, G, NK, EC	Binds both IL-1 α and IL-1 β with high affinity, as well as the IL-1 receptor antagonist	80
CDw121b	Interleukin 1 receptor type II	G, T, B, M	Binds both IL-1 α and IL-1 β with high affinity, as well as the IL-1 receptor antagonist	60–70
CDw122	Interleukin 2 receptor β chain	T, NK, B, M	Member of the cytokine receptor (hematopoietin) superfamily. Binds IL-2 with low affinity. Noncovalently associates with the CD25 molecule and the CD132 molecule (common to CD124 and CD127 molecules) to the high-affinity IL-2 receptor complex. Also part of the IL-15 receptor complex	75
CDw123	Interleukin 3 receptor α chain	M	Associates with CDw131 (common to CD116 and CDw125) to form the functional IL-3 receptor	70
CD124	Interleukin 4 receptor	(Broad)	Receptor subunit for IL-4 and IL-13 by noncovalently associating with the CD132 molecule or the IL-13 receptor, respectively	140
CDw125	Interleukin 5 receptor α chain	Eo, B act, basophils	Associates with CDw131 (common to CD116 and CDw123) to form the functional IL-5 receptor	60
CD126	Interleukin 6 receptor	T, B act, M	Binds IL-6 with low affinity. Noncovalently associates with the CD130 molecule to form the functional high-affinity IL-6 receptor	80
CD127	Interleukin 7 receptor	T	Associates with the CD132 molecule, which results in augmentation of binding affinity and internalization of IL-7	75
CDw128	Interleukin 8 receptor	G	The two identified forms are members of the rhodopsin superfamily that contain seven transmembrane domains and couple to GTP-binding proteins	58–67
CD130	gp130	(Broad)	Binds oncostatin M (OSM) with low affinity. Noncovalently associates with the CD126 molecule to form the high-affinity receptor for IL-6. Signal transducing component of the IL-11 receptor. Upon association with the leukemia inhibitory factor (LIF) receptor, the high-affinity receptor for LIF, OSM and cardiotrophin-1 is generated. This functional LIF/OSM receptor is probably converted to the ciliary neurotrophic factor (CNTF) receptor upon association with the CNTF binding protein	130

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CDw131	Common β chain	Myeloid cells, pre B	Associates either with the CDw123, the CDw125, or the CD16 molecule to form the appropriate functional receptor	120
CD132	Common γ chain	Broad	γ chain of the receptors for IL-2 (see CD25 and CDw122), IL-4 (see CD124), IL-7 (see CD127), IL-9, and IL-15. Mutation causes x-linked severe combined immunodeficiency	64
CD134	OX40	T act sub	Member of the TNF/NGF receptor family (see CD27, CD30, CD40, CD95, CD120a, CD120b, CDw137). Costimulatory molecule of T cells. Involved in T-B and T-EC interactions by binding to the OX40 ligand	48–50
CD135	flt3/flk2; STK-1	Prog sub, pre B	Belongs to the Ig and receptor tyrosine kinase family (see CD115, CD117, CD140a, CD140b). Receptor for flt3 ligand. Important receptor/ligand system for hematopoietic cell proliferation and differentiation	155
CDw136	Macrophage-stimulating protein receptor (MSPR), RON	M, G, EPC	Member of the receptor tyrosine kinase family. The mature protein is organized as a disulfide-linked α/β dimer, which is derived from a single chain pro RON. Involved in the regulation of production of blood cells, and in the development of epithelial tissue	150, 35
CDw137	4-1BB	T act	Member of the TNF/NGF receptor family (see CD27, CD30, CD40, CD95, CD120a, CD120b, CD134). Receptor for 4-1BB ligand. Seems to be important for T cell survival	30
CD138	Syndecan-1, B-B4	PC, EPC	The extracellular domain bears heparan sulfate glycosaminoglycans through which it binds both growth factors and extracellular matrix constituents. The cytoplasmic domain interacts with cytoskeletal components. Proposed to have roles in growth factor action, extracellular matrix adhesion and cytoskeletal organization that controls cell morphology	80–160
CD139		B, M, G	Not fully characterized	220+250
CD140a	α -platelet-derived growth factor (PDGF) receptor	Undetectably expressed	Belongs to the Ig supergene and receptor tyrosine kinase family (see CD115, CD117, CD135, CD140b). PDGF binding induces either homodimerization or heterodimerization with the CD140b molecule. Binds both PDGF-A and PDGF-B chains. Induces a mitogenic response	180
CD140b	β -platelet-derived growth factor (PDGF) receptor	Focal EC, stromal cell lines	Belongs to the Ig supergene and receptor tyrosine kinase family (see CD115, CD117, CD135, CD140a). PDGF binding induces either homodimerization or heterodimerization with the CD140a molecule. Binds PDGF-B chains. Induces a mitogenic response, actin reorganization and chemotaxis	180
CD141	Thrombomodulin	Myeloid cells, EC, Plt	Receptor for thrombin. Involved in regulation of coagulation	100
CD142	Tissue factor, thromboplastin, coagulation factor III	M act, EC act, EPC	Related to the IFN α receptor and the CDw119 molecule. High-affinity receptor for factor VII, and it is the essential cofactor for factor VII. Forms a ternary complex with factor VII and X to induce the extrinsic pathway of the coagulation cascade	45

Table 1 Continued

	<i>Other name (s)</i>	<i>Main reactivity of mAbs</i>	<i>Short characteristic of the CD molecule</i>	<i>Molecular weight reduced (kDa)</i>
CD143	Angiotensin-converting enzyme (ACE), peptidyl dipeptidase A, EC3.4.15.1	EC, EPC	Somatic form of ACE. Zinc metallopeptidase with specificity for the vasoactive peptides angiotensin I and bradykinin. Differentially expressed along the vascular tree. EC of arterioles, small arteries, capillaries in organs such as lung are positive. EC of large arteries and veins are mostly negative	170
CD144	Vascular endothelial cell cadherin (VE-cadherin), cadherin 5, 7B4	EC	Ca ²⁺ dependent homophilic cell adhesion molecule. It interacts with catenins which link CD144 to the cytoskeleton; this complex is crucial for the regulation of cell adhesion	130
CDw145		EC	Defined by the mAbs 7E9 and P7A5. Not fully characterized	25
CD146	Muc18/S-endo, MCAM, Mel-CAM	EC, T act sub, smooth muscle cells, melanoma cells	Member of the Ig supergene family. Potential cell adhesion molecule	130
CD147	Neurothelin, basigin, M6, EMMPRIN	Leukocytes broad, EC, Plt, red blood cells	Member of the Ig supergene family. Potential cell adhesion molecule	50–60
CD148	p260, HPTP η /DEP1	Leukocytes broad, Plt	Density enhanced protein tyrosine phosphatase-1 (DEP-1). Type III protein tyrosine phosphatase	200–260
CDw149	MEM-133	Lymph, M	Not fully characterized. Defined by mAbs MEM-120 and MEM-133	120
CDw150	Signaling lymphocyte activation molecule (SLAM), IPO-3	T sub, B sub, Thy	Member of the Ig supergene family. It is a homotypic adhesion molecule involved in T/T, T/B, B/B interaction, and thereby in the regulation of T cell and B cell activation	70
CD151	Platelet-endothelial tetra-span antigen (PETA)-3	Plt, EC, stromal cells	Member of the tetraspans family (see CD9)	27
CD152	Cytotoxic T lymphocyte antigen (CTLA)-4	T act	Receptor for CD80 and CD86. Functions as a regulator of the T cell activation	44
CD153	CD30 ligand	T act	Member of the TNF family (see CD70, CD95L, CD154). Counter-receptor for CD30	40
CD154	gp39; TRAP-1; CD40 ligand	T act, mast cells	Member of the TNF family (see CD70, CD95L, CD153). Essential for germinal center formation and for Ig class switching	39
CD155	Poliovirus receptor	M, CD34 ⁺ cells	Member of the Ig supergene family	80–90
CD156	MS2, ADAM-8	M, G	Belongs to the ADAM (a disintegrin and metalloproteinase domain) family. The extracellular region consists of a disintegrin-, metalloproteinase-, cysteine rich and EGF domain. Probably involved in loosening of cell–cell, cell–matrix contacts	69
CD157	Bst-1, Mo5	M, G, bone marrow stromal	Glycosylphosphatidylinositol-linked, CD38-like protein having both ADP-ribosyl cyclase activity and cyclic ADP-ribose (cADPR) hydrolase activity	42–50
CD158a	p58.1/p50.1	NK Sub, T sub	Receptor for HLA CW2, CW4, CW5, CW6. Killer cell inhibitory receptor (KIR) family member. p58.1 is the inhibiting form, p50.1 is the activating form; the difference is in the truncation of the cytoplasmic domain in p50.1	58.50

Table 1 Continued

	Other name (s)	Main reactivity of mAbs	Short characteristic of the CD molecule	Molecular weight reduced (kDa)
CD158b	p58.2/p50.2	NK	Receptor for HLA CW1, CW3, CW7, CW8. Killer cell inhibitory receptor (KIR) family member p58.2 is the inhibiting form, p50.2 is the activating form; the difference is in the truncation of the cytoplasmic domain in p50.2	58.50
CD161	NKR-P1A	NK, M, T sub, Thy precursors	Member of the Ca^{2+} -dependent (C-type) lectin superfamily of type II transmembrane receptors (see CD23, CD69, CD72, CD94)	30
CD162	PSGL-1, CD62 ligand	M, G, T	Counter-receptor of CD62E, CD62L and CD62P. Involved in leukocyte rolling	110
CD163	KiM8, M130, GHI/61	M	The CD163 molecule is a type I transmembrane molecule. The extracellular domain consists of nine scavenger-like repeating elements	130
CD164	MGC-24, MUC-24	T, M, G, epithelial cells, stroma cells, bone marrow cells	Sialomucin-like glycoprotein (see CD34, CD43, CD68). Involved in adhesion of hematopoietic cells to stroma cells	80
CD165	AD2/GP37	Plt, NK sub, T sub	Not fully characterized. Defined by mAbs AD2 and SN2	42
CD166	Activated leukocyte-cell adhesion molecule (ALCAM), CD6 ligand	M act, T act, Thy epithelium, neurons	Counter-receptor for CD6	100

Abbreviations: B, B-cells; act, activated; DC, dendritic cells; EC, endothelial cells; Eo, eosinophils; EPC, epithelial cells; G, granulocytes; LHC, epidermal Langerhans cells; M, monocytes; Mac, macrophages; NK, natural killer cells; PC, plasma cells; Plt, platelets; Prog, progenitor cells; sub, subpopulation; T, T cells; Thy, thymocytes. Cell types in brackets indicate weak reactivity or heterogeneous expression.

human proteins/genes. Within this database the CDs form a subgroup. The individual CD guides of PROW are written and reviewed by different experts and will be updated permanently. The CD1 family of cell surface glycoproteins is a well-defined group of non-major histocompatibility complex (MHC) encoded molecules. This nonpolymorphic cluster is the best understood of the MHC-unlinked antigen-presenting molecules. Five CD1 genes (CD1a, b, c, d and e) have been identified in humans and two genes (mCD1.1 and mCD1.2) in the mouse. However, CD1 genes and their products are evolutionarily conserved in mammals as they were identified in rats, rabbits, guinea pigs, cows and sheep.

Apparently, CD1 molecules represent a third and distinct lineage of antigen-presenting molecules that differ from MHC class I and class II molecules. Whereas CD1 molecules are structurally similar to MHC class I molecules and are associated with β_2 -microglobulin (β_2m), their expression at the cell surface requires an endocytic compartment similar to MHC class II molecules.

CD1a was fortuitously discovered in 1979 as the first human leukocyte antigen (HLA) recognized by a monoclonal antibody. Nevertheless, the most remarkable discovery regarding these molecules was reported only a few years ago when human CD1b was shown to present a nonpeptide antigen to T cells. Indeed, CD1 proteins are capable of presenting nonpeptide antigens such as microbial lipids and glycolipids as well as peptide antigens. Such novel bio-

chemical properties may reflect a specialized role for CD1 in the immune system and the potential to exploit it in vaccine development.

CD1 genes and CD1 protein structure

CD1 genes are MHC-unlinked, i.e. the human CD1 genes are encoded on chromosome 1, while HLA genes are encoded on chromosome 6. Similarly, the mouse CD1 genes are encoded on chromosome 3, whereas MHC genes are mapped to chromosome 17. The intron-exon structure of CD1 genes is similar to that of the MHC class I genes (Figure 1).

At least four human CD1 proteins (the CD1a, b c and d isoforms) are expressed on the surface of cells in association with β_2m . The protein products of these genes have been loosely classified into two groups according to their structure and tissue distribution (Table 1). The first group includes human CD1a, CD1b and CD1c, which are abundantly expressed on professional antigen-presenting cells such as Langerhans cells, dermal and lymph node cells, dendritic cells, mantle zone B cells and cytokine-activated monocytes. The second group includes human CD1d, and mouse CD1.1 and CD1.1, which are strongly expressed on the intestinal epithelium.

Amino acid homology of CD1 proteins and MHC class I and II molecules is minimal in the $\alpha 1$ domain

Figure 1 Intron-exon organization of CD1 and MHC class I and II genes. Open boxes are coding for exons. 5' UT, 5' untranslated region; L, leader sequence; TM, transmembrane domain; C, cytoplasmic domain; 3' UT, 3' untranslated region. (Reproduced with permission from Porcelli (1995).)

Table 1 CD1 molecules are classified into two groups according to their structure and tissue distribution

CD1 group	Known members	Tissue distribution
Group 1	Human CD1a, CD1b, CD1c and CD1e Sheep CD1b	Professional antigen-presenting cells such as Langerhans cells, dendritic cells, dermal and lymph node cells, mantle zone B cells and cytokine-activated monocytes
Group 2	Human CD1d Mouse CD1.1 and CD1.2 Rabbit CD1d	Intestinal epithelium, cortical and medullary thymocytes, circulating and splenic B cells, and hepatocytes

and is very limited in the $\alpha 2$ domain (especially with respect to class I proteins) (Figure 2). In the $\alpha 3$ domain, detectable homology is seen between CD1 and both MHC class I and class II proteins. The highest similarity scores in this region are with HLA-F (34%), HLA-A2 (27.8%), and HLA-DR β (25.8%). Indeed, the $\alpha 3$ domain of CD1 proteins falls within the C1 group of immunoglobulin (Ig) superfamily members.

Antigen processing and presentation

The majority of antigens presented by MHC class I molecules are generated in the cytosol after proteolysis of endogenous proteins by proteasomes. Short peptides are then transferred into the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP), and after binding to newly assembled MHC class I molecules, are transported

to the plasma membrane. Similar to MHC class I, class II molecules assemble in the ER. However, class II molecules bind antigenic peptides in endosomal structures. MHC class II antigen processing and presentation can be blocked by reagents that raise endosomal pH (such as ammonium chloride, concanamycin A or chloroquine). In the ER, MHC class II molecules associate with the invariant chain (Ii); this association is required for efficient release of MHC class II from the ER. The signals that target the class II-Ii complex to the endosomal compartment are located in the cytoplasmic tail of Ii. Upon arrival in the endosomes, Ii is degraded, allowing the peptide-binding groove of MHC class II to be exposed for loading of the antigenic peptide. Two MHC class II-like structures, HLA-DMA and HLA-DMB, play an essential supporting role in processing of antigens presented by MHC class II molecules. Class II molecules on cells with specific deletions in HLA-DM

Figure 2 A proposed domain organization of CD1 proteins in comparison to MHC class I and II proteins. ●—, N-linked glycosylation; C1, immunoglobulin C1-like domain; S-S, intradomain disulfide bonds. (Reproduced with permission from Porcelli (1995).)

genes fail to present most but not all antigens and their MHC molecules contained mostly an Ii-derived fragment designated CLIP (class II-associated Ii peptide). Recently it has been demonstrated that HLA-DM molecules facilitate the release of CLIP and the subsequent binding of other peptides to MHC class II molecules. Although not all MHC class II molecules depend on HLA-DM for antigenic loading, HLA-DM proteins appear to function as chaperones that help in the last step of MHC class II folding and antigenic peptide loading.

Despite association with β_2m , the antigen processing pathway employed by CD1 molecules is closer to that of MHC class II than to that of class I. CD1 antigen presentation is independent of TAP-1 and TAP-2. Using cells from TAP-deficient patients (TAP^{-/-}), recent studies demonstrated that CD1a and CD1c are normally expressed on the surface of epidermal Langerhans cells. In addition, normal expression of CD1a, b and c was seen on dendritic cells differentiated *in vitro* from monocytes from the same patients. Furthermore, these studies showed that CD1a molecules on the surface of the TAP^{-/-} dendritic cells were functional. Thus, this implies that either cell surface CD1 molecules are empty, or that CD1 molecules present TAP-independent antigens.

Although antigen presentation by CD1 does not require the MHC class II-like dimer, HLA-DMA/B, it is inhibitable by chloroquine and concanamycin A. In addition, recent studies demonstrate that nonpeptide antigens are processed in endocytic compartments. CD1b molecules appear to arrive at the endosomal compartment through at least two distinct routes: 1) a major recycling pathway, where CD1b

molecules are endocytosed at the plasma membrane and subsequently delivered to the MHC class II compartment (also called MIIC); this pathway is mediated by the cytoplasmic domain of CD1b molecules; and 2) a pathway comparable to MHC class II-Ii targeting to the endosomes; however, the signals that target CD1 molecules to MIIC appear to be a tyrosine-based motif in its cytoplasmic tail.

CD1-restricted antigens

Among the most unique features of the CD1 family members is the ability of certain CD1 molecules to present nonpeptide antigens to T cells. At least three classes of antigens have been shown to be presented by CD1 molecules, i.e. a lipid moiety, a lipoglycan and peptide antigens were recognized by CD1-restricted T cells.

In 1994, a group of scientists at Harvard University described the first CD1-restricted antigen as a protease-resistant moiety that copurified with the lipid fraction of the mycobacterial extract. Biochemical analysis of this antigen showed that it is a member of the mycobacterial family of mycolic acids (Figure 3). The fact that mycolic acid is found in the cell wall of several bacterial species such as *Nocardia* and *Corynebacterium* spp. suggests that CD1 molecules may present antigens derived from bacterial pathogens other than mycobacteria. A year later, these findings were extended by describing two *Mycobacterium leprae*-specific CD1b-restricted human T cell lines that recognize lipoarabinomannan (LAM), a glycolipid from the mycobacterial cell wall, and do not cross-react with mycolic acid. This molecule belongs to the lipoglycan family and is com-

Figure 3 Mycolic acids are high molecular weight α -branched, β -hydroxy fatty acids that are components of the cell wall of all mycobacteria. All known mycolic acids have the basic structure $R^2\text{CH(OH)CHR}^1\text{COOH}$ where R^1 is a C-20–C-24 linear alkane and R^2 is a more complex structure of 30–90 carbon atoms that may contain various numbers of carbon–carbon double bonds and/or cyclosporane rings, methyl branches and oxygen function groups such as $\text{C}=\text{O}$, $\text{CH}_3\text{OCH}=\text{COOH}$. Three principal categories of mycolic acid are known, i.e. corynomycolic acids (C-28–C-40), nocardomycolic acid (C-40–C-60) and mycobacterial mycolic acids (C-60–C-90), produced by strains of *Corynebacterium*, *Nocardia* and *Mycobacterium*, respectively.

Figure 4 Mouse CD1 binds peptides with a sequence motif comprising aromatic, bulky and hydrophobic amino acids with an overhanging NH₂-terminus. The majority of these long peptides include aromatic residues at positions 1 and 7 and an aliphatic residue in position 4. F, Phenylalanine; W, tryptophan; L, leucine; I, isoleucine; M, methionine; X, any amino acid.

posed of a hydrophobic lipid-containing phosphatidyl inositol group attached to a large and complex hydrophilic heteropolysaccharide. Further studies using chemically modified LAM and related compounds showed that both carbohydrate and lipid components of the antigen were required for presentation and/or T cell recognition. In addition, these two T cell lines differed in their ability to recognize LAM purified from different species of mycobacteria, suggesting a significant level of specificity in CD1-restricted T cell responses. This distinct recognition may arise from subtle variations in the lipid and carbohydrate moieties of LAM.

The previous examples suggest that CD1 proteins could have evolved to present nonpeptide lipid antigens to T cells. However, using random peptide phage displayed libraries, mouse CD1 was shown to bind peptides with a sequence motif comprising aromatic, bulky and hydrophobic amino acids with an overhanging NH₂-terminus (Figure 4). The study identified several dozen peptides which appear to be of immunological relevance as they can elicit specific CD1-restricted CD8⁺ cytotoxic T lymphocytes (CTLs). The length of these peptide antigens was not critical; however, the majority of these peptides

include aromatic residues at positions 1 and 7 and an aliphatic residue in position 4. The characteristics of the mouse CD1-peptide interactions are similar to the interactions of MHC class II molecules with its ligands. For example, in common with class II ligands, mouse CD1 appears to prefer long peptides with hydrophobic and bulky amino acids at certain positions. In addition, the affinity of interaction of these peptides is similar to that of naturally processed peptides copurified with class II molecules.

Although mouse CD1 has been shown to bind peptides, it is not known if mycolic acid and the other lipoglycans directly bind to CD1b. In addition, it is not yet known whether CD1b presents one or more members of the mycolic acid families to T cells as a processed or intact molecule, or as part of a modified epitope.

Interestingly, the amino acid sequence of all known CD1 molecules from various mammalian species, as well as another MHC-unlinked molecule, neonatal Fc-receptor (FcRn), share a proline at position 162 in the $\alpha 2$ helix. Recent crystallographic studies of FcRn showed that Proline 162 induces a kink that closes the peptide-binding groove, thus preventing peptide binding. If this kink is found in CD1 molecules, then it is possible that the interaction between CD1 molecules and their ligands is different from that known for conventional MHC class I molecules. Also, it may resemble that of MHC class II-superantigen association. In addition, the full range of antigens presented by the CD1 molecules is not yet known and the natural ligands remain to be defined. However, studies from several laboratories support the hypothesis that CD1 molecules contain a hydrophobic pocket between the $\alpha 1$ and $\alpha 2$ domains capable of accommodating lipids, glycolipids or

Table 2 Comparison between CD1, MHC class I and MHC class II molecules

	CD1 Molecules	MHC class I	MHC class II
Antigen processing and presentation			
TAP-1/TAP-2 requirement	No	Yes for the majority	No
HLA-DMA/B requirement	No	No	Yes for the majority
Chloroquine sensitivity	Yes	No	Yes
Invariant chain (Ii) requirement	No	No	Yes
Endosomal compartment passage	Yes	No	Yes
ER to endosome targeting	Signal in the cytoplasmic tail	Not applicable	Signal in the Ii
$\beta_2\text{m}$ association	Yes	Yes	No
T cell recognition	CD4 ⁻ /CD8 ⁻ , CD8 ⁺ , CD4 ⁺	Mostly CD8 ⁺	CD4 ⁺
Nature of antigens presented	Lipid, glycolipid and long hydrophobic peptides	Mostly peptides, 8–10 amino acids long	Mostly peptides, 8–20 amino acids long

hydrophobic peptides. It is clear that further biochemical studies and the determination of the crystal structures of both mouse and human CD1 are needed to elucidate these issues.

Role of CD1 in the immune system

The initial reports implicating CD1 in T cell function demonstrated that human T cell clones expressing either α/β or γ/δ T cell receptors (TCRs) recognized tumor cells expressing specific isoforms of human CD1. These CD1-restricted T cells were phenotypically CD4⁺CD8⁻ or double negative (DN) T cells. CD1b-restricted proliferative and cytotoxic responses of human DN- α/β ⁺ and DN- γ/δ ⁺ lymphocytes specific for *M. tuberculosis* and *M. leprae* were seen in cells isolated from blood of normal humans. Also, CD1-restricted T cells specific for mycobacterial antigens have been found among CD8⁺ TCR- $\alpha\beta$ ⁺ T cells. In addition, mouse NK1⁺ TCR- $\alpha\beta$ ⁺ T cells, which appear to be entirely CD1 restricted, were isolated recently. These T cells were either DN or CD4⁺. Thus, it is now accepted that CD1 recognition is broadly distributed among T cell subsets. The different biochemical features of the various members of the CD1 family and the wide spectrum of recognition by T cell subsets indicate that CD1 molecules may subserve several specialized functions in the immune system, such as presentation of hydrophobic ligands (lipids or peptides) and/or regulation of the classes of immune responses.

The mouse MHC class I molecule, H2-M3, was the first definitive example of a specialized molecule in antigen presentation. H2-M3 preferentially binds hydrophobic N-formylated peptides, which make it suited to the presentation of antigens derived from intracellular pathogens. CD1 and H2-M3 molecules share a common feature, i.e. both bind and present hydrophobic antigens of bacterial origin. While both CD1 and H2-M3 may have evolved to combat microbes, each of these molecules seem to use different antimicrobial strategies. The antigens presented by H2-M3 are from the NH₂-terminus of prokaryotic proteins and appear to be intracellular in nature. In contrast, CD1 molecules seem to bind bacterial cell wall lipids that come from the extracellular milieu. Interestingly, H2-M3 has not been found in species other than rodents (including humans). Thus, human group I CD1 molecules, may accomplish the role assigned to H2-M3 in the mouse.

Autoreactive CD1-restricted T cells (NK1⁺) have been identified in normal unimmunized mice. Although this rare T cell population includes the DN phenotype, the majority are CD4⁺ cells. A prominent subset of these CD1-specific cells uses an invariant

TCR α chain in conjunction with a restricted set of TCR V β families. During their differentiation in the thymus, these cells acquire several unique properties, i.e. they express natural killer cell receptors, and they display unusual cytokine secretion functions. In particular, the CD4⁺ subset secretes large amounts of interleukin 4 (IL-4) upon primary stimulation, within an hour of TCR engagement. Several studies indicated that NK1⁺ T cells could potentially influence the TH1/TH2 profile of the immune response, and thus could act as natural suppressors of graft-versus-host disease, mediate acute graft rejection, or regulate autoimmune symptoms in lupus and diabetes. As yet, however, there is no physiological phenomenon that these T cell subsets are associated with.

CD1b is abundantly expressed in the lesions of patients with the self-healing form of leprosy (where interferon γ secreting TH1 CD4⁺ cells are recruited) but not with the lepromatous form (where TH2 CD4⁺ cells predominate). Thus, it is suggested that CD1b expression may determine the TH1/TH2 set of specialized cytokines produced in response to *M. leprae*. Mycobacterial lipids are an ideal foreign target; indeed, mycolic acid is an active component of one of the most powerful adjuvants (Freund's complete adjuvant). Therefore, it is postulated that early production of cytokines by CD1b-restricted, mycobacterial-specific T cells may jump-start the immune response or may determine its TH1 differentiation. The possible roles of CD1-expressing cells and NK1⁺ T cells in influencing the TH1/TH2 differentiation and development pathway remains to be fully understood.

The oligomorphic CD1 proteins are a third and distinct group of antigen-presenting molecules (Table 2) that are conserved in all mammalian species tested. Monomorphic and oligomorphic antigen-presenting molecules may be more effective in inducing a protective immune response, and for potential vaccine design, than their polymorphic counterparts. Whereas the latter group might bind tens of antigens with different sequences, the former binds a single or very limited number of antigens. A single peptide or a microbial lipid, in the case of CD1 proteins, might be sufficient to induce this protective response in all recipients. Thus, CD1 proteins are definitive candidates for antigen-presenting molecules in vaccination strategies intended to induce a universal CTL response.

CD2

Stefan C Meuer, Ruprechts-Karls-Universität, Heidelberg, Germany

CD2 is a glycoprotein of 50 kDa expressed by the vast majority of non-B lymphocytes in humans. In the mouse, unlike in humans, CD2 is also present on B lymphocytes and, in the rat, on splenic macrophages. CD2 appears at the earliest level of T lineage ontogeny and demonstrates a remarkable structural conservation among species. Several differentially glycosylated forms have been found on the cell surface of human non-B lymphocytes. In the mouse, two distinct isotypic forms of CD2 exist in different strains.

Structure

The CD2 gene maps to the human chromosome 1. Analysis of CD2 cDNA clones indicates a cleaved signal peptide of 24 amino acids, an extracellular segment of 185 residues, a transmembrane domain of 26 residues and a cytoplasmic region of 116 residues. Restriction analysis and sequencing of genomic DNA shows that the gene is divided into five exons, one encoding the signal peptide, two encoding the two extracellular domains, one encoding the transmembrane domain, and one encoding the intracellular domain. On the basis of significant primary

sequence homology, a relationship of CD2 to the Ig superfamily has been proposed. Secondary structure predictions reveal a mix of α helical and β sheet structures.

Ligands

Employing transfection of cells with mutagenized plasmids or human CD2 chimeric and mutant proteins, distinct CD2 epitopes are defined by monoclonal antibodies and mapped to one of the Ig-like domains of the CD2 ectodomain. CD2 binds to the ubiquitously expressed cell surface glycoprotein, CD58, which is present on many human cell types including antigen-presenting cells and endothelial cells. A sheep homolog of CD58 exists which binds to human CD2, providing the molecular explanation for the fortuitous observation that human T lymphocytes and sheep blood cells spontaneously form rosettes. A second structurally related ligand, CD48, binds to CD2 but with an affinity two orders of magnitude weaker than that of the CD2/CD58 interaction. CD59 is also thought to bind to CD2.

Interactions of CD2 with its ligands are mediated through the N-terminal membrane distal Ig-like

domain. The precise role of the second or membrane-proximal Ig domain has not been elucidated in depth, although activation of T cells in response to paired mitogenic combinations of CD2-specific monoclonal antibodies requires that one monoclonal antibody is directed against an epitope (CD2R) within or closely related to this region.

Role of CD2

Expression of CD2 on resting versus activated human T cells not only differs from a quantitative point of view (CD2 on resting T cells: approximately 30 000 molecules per cell; CD2 on activated T cells: approximately 200 000 molecules per cell) but also with regard to expression of the CD2R epitope, which is only found on activated T cells and exposed as a consequence of ligand-induced conformational changes within the CD2 ectodomain.

The involvement of CD2 in T lymphocyte adhesion and activation is well documented. In addition to providing accessory signals for T cell receptor-mediated activation of lymphocytes, *in vitro* activation in the absence of direct stimulation through the T cell receptor using mitogenic combinations of CD2-specific monoclonal antibodies has been described. CD2 has been shown to play a role in potentiating T cell responses to the cytokines interleukin 1 (IL-1), IL-6 and IL-12 and to be involved in the regulation of T cell anergy. In this regard, perturbation of particular regions of CD2 can inhibit T cells and this inhibition is independent of the disruption of the adhesion function of CD2 with its ligands. Rather, polyclonal T cell hyporesponsiveness which persists long after the recovery of CD2 cell surface expression may be due to an inhibitory signal which is delivered to T cells through CD2. T cell anergy correlates with a loss of the CD2R epitope expression but not CD2 expression. Reversal of anergy following culture with IL-2 is induced when challenged with antigen and CD58 and this coincides with the reappearance of the CD2R epitope. Among the accessory T cell molecules examined so far, CD2 appears to be unique in its ability to participate in the reversal of anergy.

Signaling

CD2 itself has no enzymatic activity but transmits signals in part via the T cell receptor/CD3/ ζ complex through its interaction with the ζ chain and CD3 ϵ and also through other unknown pathways as suggested by the tyrosine phosphorylation of distinct

intracellular substrates and the serine dephosphorylation and nuclear translocation of cofilin, a cyclosporine-insensitive event. Of particular interest is the interaction of CD2 with the tyrosine phosphatase CD45. CD2 also interacts with the tyrosine kinases p56^{lck}, p59^{fyn} and the ζ subunit of the T cell receptor/CD3/ ζ complex, each of which have been shown to be targets for CD45 phosphatase activity. Indeed it is possible that CD2 regulates T cell activation by bringing CD45 into the proximity of these molecules.

Perturbation of CD2 and/or its associated signaling molecules provides a means for positively and negatively regulating T cell responses and may turn out to represent a central component of therapeutic efforts to regulate tolerance.

CD3

Alan Tunnacliffe, Anglia Research Foundation, Cambridge, UK

Originally known as T3, CD3 was identified by Kung and colleagues in 1979 and was one of the first groups of human T lymphocyte surface antigens identified using monoclonal antibodies. It was subsequently shown that antibodies against CD3 could, depending on the conditions used, either stimulate T cells to divide or inhibit the development of effector functions such as cytotoxicity. Therefore, it was apparent early on that CD3 had an important role in T cell function. Initially, CD3 was thought to consist of a single polypeptide, but later analysis demonstrated its three-chain nature (CD3 γ , δ and ϵ) and its close association with T cell antigen receptor (TCR) heterodimers. This established the CD3 molecules, together with other invariant subunits (ζ and η), as part of the core TCR. Although the TCR $\alpha\beta$ or $\gamma\delta$ heterodimers govern the antigen recognition capability of the TCR, signal transduction and the regulation of TCR function are mediated through the invariant subunits.

Structure and assembly of TCR invariant subunits

Investigation of the structure of the TCR has been an area of intense activity, since such studies should provide insight into the molecular details of receptor function, but much remains to be learned. The current picture is of an elaborate structure comprising at least four invariant polypeptides forming a complex with the antigen-binding heterodimer. The most common form of the $\alpha\beta$ -type core receptor is likely to have the stoichiometry $\alpha\beta\gamma\delta\epsilon_2\zeta_2$, where the γ , δ and ϵ chains are the CD3 subunits proper, being specific to the TCR, and ζ is the most prevalent member

of a family of similar molecules which include η and the γ chain of some Fc receptors. The structural characteristics of the most important of these molecules are given in Table 1.

The cDNAs for the three CD3 molecules were cloned in the mid-1980s and examination of the predicted amino acid sequences suggested that they form a small family of homologous integral membrane proteins, with γ and δ showing a particularly high degree of relatedness to each other. Close linkage of the CD3 genes is consistent with their evolution from a common ancestral gene. The extracellular domain of each chain possesses some sequence similarity with immunoglobulin (Ig) and the potential to arrange stretches of β sheet as a partial Ig fold. The CD3 proteins, therefore, like TCR $\alpha\beta$ and TCR $\gamma\delta$, are members of the Ig superfamily. The transmembrane regions of the CD3 molecules each contain an acidic amino acid within the stretch of hydrophobic residues, an unusual feature which is probably significant given the presence of corresponding basic residues in the transmembrane regions of TCR heterodimers. Although it is unlikely that full ionization of acidic and basic side-chains takes place in the hydrophobic environment of the plasma membrane, interactions between the transmembrane sequences of heterodimers and the CD3 subunits may help to stabilize the TCR complex. The sequences of the cytoplasmic domains of the CD3 subunits show little relatedness to other known proteins, but all contain the tyrosine-containing Reth motif implicated in signal transduction, which is also found three times in the ζ cytoplasmic domain and in other receptor-associated polypeptides including the surface IgM-associated Ig- α and Ig- β proteins, and the β and γ subunits of Fc ϵ RI.

Table 1 Structural data on TCR invariant subunits

Subunit	Molecular weight (kDa)		Ig superfamily?	Glycosylated?
	Human	Mouse		
CD3 γ	25	21	Yes	Yes
CD3 δ	20	28	Yes	Yes
CD3 ϵ	19	25	Yes	No
ζ	16	16	No	No
η	Not encoded	22	No	No

In mouse, the vast majority (80–90%) of the ζ chain exists as a disulfide-linked homodimer, but can also form heterodimers with the related η , γ and (possibly) θ chains. This leads to the formation of several isoforms of the mature TCR complex within a single T cell, with the potential for functional variation between forms. Cloning and sequencing predict a structure for ζ which is markedly different from that of the CD3 proteins. One feature which ζ does share with CD3 subunits is the acidic residue in its transmembrane region. Otherwise, it has a minimal extracellular domain, consisting of only nine amino acids including the cysteine responsible for disulfide linkage, and an intracellular domain with a consensus sequence for ATP binding and multiple (six in mice; seven in humans) tyrosines, whose phosphorylation results in a dramatic apparent increase in M_r to 21 kDa. Intriguingly, η and θ derive from the same gene as ζ , by alternative mRNA processing, although γ is encoded by a separate, though linked, gene. The significance of the η , γ and θ chains is unclear, however, given that η has been demonstrated to be absent from human T cells.

Study of the assembly of a multisubunit complex such as the TCR is hindered by a number of problems. First, the receptor is built up of several transmembrane proteins and requires translocation of subunits across a membrane for its formation. Therefore, it is difficult to study interactions of purified proteins in solution. Furthermore, all TCR components (excepting η) may need to be present for efficient complex formation. However, the combination of several approaches including the examination of immature T cells and T cell lines, together with the analysis of partial receptor complexes, has provided considerable information.

Thymocytes express CD3 γ , δ and ϵ at an early stage in their development, before the TCR α and β genes have completed their rearrangements: between days 14 and 16 of mouse fetal thymus development, and from week 10.5 in human fetal thymus. In humans, there is also evidence for expression of the

CD3 genes from week 7 in fetal liver, prior to colonization of the thymus. Thus, the CD3 genes are among the earliest T cell lineage genes to be expressed. Without the antigen-binding heterodimer proteins, immature thymocytes do not express significant levels of surface CD3. Cell lines lacking either TCR α or β also fail to deliver CD3 to the cell surface, or do so inefficiently. Mutant cell lines defective in ζ production express only 5% of normal cell surface receptor levels. Cumulatively, these data indicate that a ζ_2 -type receptor requires most, and possibly all, subunits for efficient transport to the plasma membrane.

During assembly of the TCR complex, the individual components form partial complexes, a situation which can be mimicked experimentally when genes for the individual subunits are transfected in various combinations into heterologous cells. Such partial complexes are largely unstable and most are rapidly degraded within the cell before reaching the mid-Golgi, but they can be studied to reveal likely subunit interactions within the mature TCR complex. Thus, observed isolated pairwise combinations are CD3 $\gamma\epsilon$, CD3 $\delta\epsilon$, but not CD3 $\gamma\delta$, which is interpreted as evidence against close contact between the CD3 γ and δ chains. Intracellular TCR complex assembly may be aided by the molecular chaperone proteins TRAP and calnexin, which are thought to mediate correct subunit interactions. Whether the TCR α and β chains dimerize before association with CD3 molecules may depend on which cells are examined, but in immature double-positive thymocytes this is thought not to occur. Instead, trimeric complexes, $\alpha\delta\epsilon$ and $\beta\gamma\epsilon$, form first which then combine via $\alpha\beta$ dimerization and finally associate with the ζ_2 dimer giving a stoichiometry of $\alpha\beta\gamma\delta\epsilon_2\zeta_2$. This is supported by transgenic mouse experiments which indicate one TCR α , one TCR β and two CD3 ϵ chains per complex. A model structure for the core receptor based on these data is shown in Figure 1.

Figure 1 A model of the T cell antigen receptor ($\alpha\beta\gamma\delta\epsilon\zeta_2$ -type) showing an arrangement of subunits compatible with current data. A transverse section through the plasma membrane is shown. Disulfide bonds between α and β , and between ζ subunits, are shown as solid lines.

Function of TCR invariant subunits

A critical early finding was that monoclonal antibodies to CD3, most of which recognize the CD3 ϵ chain, were able to activate resting T cells in the presence of monocytes bearing appropriate Fc receptors. Antibodies directed to the $\alpha\beta$ heterodimer can behave similarly. Thus, a T cell bridged to an antigen-presenting cell via TCR/mAb/FcR reacts in a manner analogous to the physiological situation, where the link is TCR/Ag/MHC (major histocompatibility complex). For signaling through the TCR, therefore, some form of cross-linking or partial immobilization of the receptor is necessary, which need not be dependent on specific antigen recognition. This signaling process takes place through the invariant subunits of the TCR, since the heterodimeric antigen-binding chains themselves have very small cytoplasmic domains which are unlikely to have more than an anchoring function. In peripheral T cells, full activation also requires signaling through the costimulatory CD28 molecule by the B7-1/B7-2 antigen on B cells and macrophages. Signaling through the TCR alone results in the functionally unresponsive state known as anergy.

T lymphocyte activation involves multiple intracellular events, all leading to transition from the quiescent G_0 phase of the cell cycle into G_1 and induction of interleukin 2 (IL-2) secretion and IL-2 receptor expression. T cell growth, involving pro-

gression from G_1 to S phase and mitosis, is then controlled by IL-2 binding to the IL-2 receptor. At least two signaling pathways are thought to result from TCR occupancy, the first routing through the G protein p21^{ras}, and the second through phospholipase C. Both pathways act synergistically with CD28-derived signals to effect action of the transcription factor NF-AT1 (nuclear factor of activated T cells) on, for example, the IL-2 gene.

During antigen recognition by the TCR on a CD4⁺ helper T cell, the coreceptor molecule CD4 is recruited into the receptor complex, having associated with monomorphic sites on the MHC class II molecule of the antigen-presenting cell. The Src family protein tyrosine kinase p56^{lck} associates with CD4 and, in one model of the molecular consequences of antigen binding, p56^{lck} phosphorylates the CD3 and ζ chains on the tyrosine residues within their Reth activation domains. This promotes association of the TCR with the T cell-specific protein tyrosine kinase ZAP-70 through its SH2 domains, when ZAP-70 itself becomes phosphorylated and provides a signal to both p21^{ras} and phospholipase C pathways via intermediate protein species.

The structure of the TCR thus reflects its two major functions of antigen recognition and signal transduction, with the latter role being governed by the invariant chains. The CD3 proteins, together with the ζ chain, must interact with other cell surface molecules, including CD4 and CD8, and several intracellular proteins such as p56^{lck} and ZAP-70, as well as other tyrosine and serine/threonine kinases. It is now apparent that the complexity of the TCR is not unique, with other receptors governing cellular activation, such as the B cell antigen receptor (surface IgM), the Fc receptors and the IL-2 receptor, also having oligomeric structures commensurate with their complex function.

CD4

Rafick Pierre Sekaly and Ronald Rooke, Montreal Institute of Clinical Research, Immunology Laboratory, Montreal, Canada

The cell surface glycoprotein CD4 is expressed on a subpopulation of mature T lymphocytes, where its presence is tightly correlated with recognition of major histocompatibility complex (MHC) class II antigens. It is also present on various other cell types.

Structure

The CD4 molecule is an elongated (125 Å × 25–30 Å) cell surface glycoprotein that is conserved among various primates and rodents, e.g. 79% amino acid identity between mouse and human (Table 1). It is made up of four extracellular domains (D1–D4). The N-terminal, outermost domain (D1) consists of nine β strands disposed in the topology of variable immunoglobulin domains. Crystallography of the D1–D2 fragment has confirmed that the last strand of D1 runs directly into the first strand of D2, which brings both domains in close contact and confers rigidity to this part of the molecule (Figure 1). Crystallographic and proteolytic studies have shown that a short, hinge-like region bridges the D1–D2 fragment of CD4 to the D3–D4 part. The membrane proximal fragment, comprising the D3–D4 domains, is referred to as a connecting peptide. It is made up of two additional, degenerate, v-like domains that also make up a rigid structure. Recently, the four extracellular domains of the human CD4 molecule have been crystallized. This work has confirmed the presence of the hinge region

between D2 and D3. More interestingly, in all crystals obtained, the CD4 appears as a dimer (H. Wu and W. Hendryckson, personal communication). The highly basic cytoplasmic tail is the most conserved domain in the molecule. Three serine residues may serve as regulatory phosphorylation sites. The D1 domain is encoded by two exons, while D2–D4 are encoded by individual exons. The human gene is made up of nine exons and eight introns and spans 33 kb, while the murine gene includes ten exons covering 26 kb.

Expression

The full length 3.7 kb CD4 transcript, along with the expression of the protein on the cell surface, was identified initially in thymocytes and mature T lymphocytes in mice and humans. However, CD4 is also seen on human macrophages, Langerhans cells, neuronal and glial cells and some Epstein–Barr virus-transformed human B cell lines. CD4 is found as a monomer on the cell surface. The presence of a smaller 2.7 kb transcript has been described in the mouse forebrain, cortex and striatum. The predicted protein from this smaller mRNA would be a truncated form of mouse CD4 beginning at amino acid 214 (within the connecting peptide) and continuing through the normal cytoplasmic tail. This smaller transcript has also been seen in human brain tissue. The significance and function of this truncated CD4

Table 1 Comparison between human and murine CD4 genes and molecules

	MW (kDa)	Protein (AA)	Leader (AA)	Extracellular (AA)	Transmembrane (AA)	Cytoplasmic (AA)	Cysteines	Glycosylation (sites)	Chromosome	Gene size (kb)

Figure 1 Crystal structure of CD4. The figure was generated using Molscript (Kraulis PJ (1991) *Journal of Crystallography* **24**: 946–950) according to X-ray diffraction coordinates published by Rye SE *et al* (1994) *Structure* **2**: 59–74 for D1 and D2, and by Brady RL *et al* (1993) *Science* **260**: 979–983 for D3 and D4. Domains 1 and 2 are from the human molecule while domains 3 and 4 are from the rat molecule. The hinge region is not shown.

mRNA are not known. Littman and coworkers have identified and characterized a T cell-specific enhancer located 13 kb upstream of the transcriptional initiation site of the mouse and human CD4 genes. They also have demonstrated the existence of an intronic regulatory region located between the first and second exons of the murine gene. The element is orientation and position independent. This negative regulatory region functions in combination with heterologous *cis*-acting regulatory elements, indicating that it is a developmentally regulated transcriptional silencer.

Interactions

Early studies suggested that CD4 might have signal transduction as well as ligand-binding capabilities. The advent of transgenic and knockout animals has confirmed and significantly extended these results, showing that the CD4 molecule is involved in a number of crucial steps during the lifespan of T cells. It is obvious that to play such a central role in the choices made by T cells, the CD4 molecule must interact with many other molecules.

MHC class II molecule

Doyle and Strominger provided the first strong evidence for physical binding between CD4 and class II MHC molecules. This was done with the use of transfected cells, which also indicated that this adhesion can take place in the absence of the T cell receptor (TCR). By using a class I (D^d) specific, CD4⁺ T cell hybridoma, Gay and coworkers investigated the role of CD4 in T cell activation. These experiments correlated the interaction of CD4 and class II MHC with an enhanced T cell activation. More recently, mutagenesis studies indicated CD4 affinity changes when residues 110, 137, 140, 141 and 142 of the solvent-exposed loop of the β 2 domain of class II were altered. Moreover, peptides with the sequence of the β 2 domain residues 134–148 (less so for 138–152) can bind CD4. From these studies and the fact that no natural polymorphic variant of MHC class II proteins have been identified that fail to bind CD4, it has been assumed that CD4 interacts with a relatively invariant part of the β 2 domain of class II. This idea has recently been challenged by Fleury and coworkers, who associated crystallographic and functional data obtained from class II molecules with varying affinities for CD4. They mapped polymorphic residues between positions β 180 and β 189 that can exert a dramatic influence on the interaction with CD4; this could contribute to the predominance of certain DR alleles or isotypes in antigen-restricted responses.

Moreover, König and coworkers have also added to our view of the interaction between CD4 and MHC class II by demonstrating that a second surface-exposed segment in the $\alpha 2$ domain of class II is also critical for the function of CD4. Both these reports are in accordance with the crystallographic data and suggest that in order for the CD4 molecule to contribute efficiently to signal transduction, it has to dimerize or oligomerize.

On the other hand, the class II contact residues on the CD4 remain controversial and will only be solved by cocrystallization of CD4 and class II. Different regions throughout D1, D2 and D3 domains have been suggested. A recent study making use of alanine-scan mutants showed that residues from both lateral faces of D1 and from one loop of D2 are involved in the interaction. This suggests an extended region of contact with the membrane-proximal lateral face of the class II molecule. These results are also consistent with an oligomerization event during the interaction.

The efficacy of interspecies interactions of human and murine CD4 with murine or human class II MHC molecules has also been a matter of debate. Sequence comparisons among human (hCD4), murine (mCD4) and rat CD4 show that residues that are implicated in the overall conformation are conserved, suggesting they will adopt similar three-dimensional structures. It was found that hCD4 and mCD4 can function to a comparable extent with at least five different class II MHC and four different mouse class II MHC molecules. Moreover, this work indicates that the structural features of this cross-species interaction are strongly conserved. These data confirm previous experiments which used transgenic animals that express various HLA class II proteins and showed that the interaction between HLA class II and mouse CD4 molecules is sufficient in provoking peptide-specific, HLA class II restricted T cell responses.

T cell receptor

Various approaches have led to the conclusion that the CD4 molecule can also physically associate with the TCR. The first evidence came from the observation that under certain circumstances, CD4-specific antibody can inhibit T cell responses. Other groups have shown that cocapping and comodulation of CD4 and TCR/CD3 at the cell surface can be induced with CD3-specific antibodies. Energy transfer experiments suggest that one TCR molecule associates with more than one CD4 in a single receptor complex. This association results in an enhanced avidity of the TCR complex for recognition of antigen-MHC class II complex and increased T cell

responsiveness. However, the molecular nature of the TCR-CD4 interaction remains poorly understood, although it is presumed to involve the membrane-proximal D3 and D4 parts of CD4.

p56^{lck}

The availability of monoclonal antibodies directed against CD4 and the TCR/CD3 complex provided strong evidence for a role of these molecules in the T cell antigen recognition and effector function. While the TCR itself does not have intrinsic protein tyrosine kinase (PTK) or phosphatase functions, an src-related PTK, Lck, is physically associated with a distinct sequence in the cytoplasmic domain of CD4. A region towards the amino-terminal end of p56^{lck} containing a stretch rich in negatively charged amino acids is believed to form ionic bonds with basic residues found within a conserved consensus sequence in the cytoplasmic domain of CD4. Moreover, p56^{lck} gains kinase activity when aggregated on the cell surface. p56^{lck} is anchored to the cytoplasmic face of the plasma membrane through a myristylated amino-terminal glycine. In lymph node cells, 75–95% of cellular Lck is associated with CD4. Conversely, 30–40% of membrane CD4 is bound to Lck. This kinase is activated by receptor cross-linking, which in turn induces phosphorylation of numerous targets. p56^{lck} serves to phosphorylate TCR ζ and possibly CD3 γ, δ, ϵ chains. By acting on TCR ζ , p56^{lck} initiates an activation cascade by enabling the receptor to recruit downstream molecules. Also, it has been proposed that CD4-associated p56^{lck} anchors CD4 and the stimulated TCR/CD3/ ζ complex to the same MHC molecule.

HIV-1 proteins

The CD4 molecule also plays an important functional role in the course of human immunodeficiency virus 1 (HIV-1) infection. Recent reports have demonstrated that the CD4 protein is not only the cellular receptor for HIV-1 but also participates actively in postbinding events important for infection and cell fusion. Mutagenesis and monoclonal antibody studies have shown that the region spanning amino acids 40–60 of the D1 domain of CD4 is the part of the molecule directly in contact with the viral gp120 for all isolates examined, with residues Phe43 and Arg59 being particularly important. However, the gp120-CD4 combining site is not universally conserved in its molecular details. A 15–100-fold range in affinities for CD4 have been reported. This reflects a complex situation that can depend on glycosylation, oligomerization of receptors, sequence variations and/or involvement of other cellular components, which ultimately contributes to viral tropism and

cytopathicity. It has also been shown that mutants in D3 can abrogate the binding of gp120. Moreover, Healey and colleagues reported that by blocking viral access to Gln425 and Gln428 they could block steps subsequent to the viral binding without affecting binding of the virus. It has been speculated that the hinge region in CD4 may be necessary to bring gp41 close to the target membrane. To test this hypothesis, a panel of point mutations and small deletions spanning the hinge region of CD4 were generated, transferred into a CD4⁺, HIV-1 susceptible T cell line, and their individual capacity to render this cell line infectable by HIV-1 assessed. Syncytia formation was also examined. This study clearly demonstrated that the hinge region of CD4 is necessary for HIV-1-induced cell fusion but not for infection. This confirmed the data from a number of groups that movement of this region is required for fusion. A region of the D1 domain of human CD4 has also been shown to participate in these events. This stems from the observation that although they share the same affinity for gp120 and susceptibility to HIV-1 infection, unlike their human homolog, the CD4 molecules from chimpanzee and rhesus monkey do not support syncytia formation. Complementary sequence exchange mapped the fusion determinant to Glu87 of the human CD4. At least three other HIV-1 proteins interact with the CD4 present at the cell surface and have been shown to be involved in its downmodulation. In HIV-1 infected cells, newly synthesized CD4 molecules are retained in the endoplasmic reticulum by a phenomenon termed receptor interference. This is the result of the formation of a complex between new CD4 and the viral gp160-env protein in the endoplasmic reticulum. The retained molecules of CD4 are degraded in this compartment by a mechanism induced by another HIV-1 protein, vpu. Another viral protein interacting with CD4 is nef. HIV-1-nef is a 206 amino acid, cytoplasmic protein that is nonessential for viral replication and associates with the plasma membrane through an N-terminal myristic acid. It is responsible for the loss of CD4 from the cell surface by inducing its endocytosis and ultimately resulting in its lysosomal degradation. This phenomenon was shown to occur early in the course of the infection, before gp160-induced receptor interference. It is mediated by a dileucine motif similar to endocytosis and lysosomal degradation signals, contained in the membrane-proximal 20, residues of the CD4 cytoplasmic tail.

Function

It is believed that the encounter between a TCR and its antigen involves a low-affinity interaction. T cells

have circumvented this problem by making use of coreceptors. In the case of a T cell that expresses a TCR recognizing antigenic peptides in the groove of a class II MHC molecule, this coreceptor function is fulfilled by CD4. If the TCR recognizes a class I MHC molecule, the coreceptor is CD8. By acting synergistically with the TCR, the coreceptors induce signal transduction events at low levels of receptor occupancy. T cells that go through maturation steps in the thymus are bipotential and can differentiate either along the CD4⁺ (helper) pathway or the CD8⁺ (cytotoxic) pathway.

Early work addressing the role of the CD4 coreceptor in thymocyte differentiation made use of monoclonal antibodies specifically directed towards CD4. Although most of these experiments were instrumental in describing the coreceptor and/or cosignaling functions of CD4, they are at odds with more contemporary data using mouse lines containing either disrupted genes or transgenes. Indeed, the latter models have generated good evidence that thymocyte commitment is a stochastic event. It follows that no distinct TCR-mediated signals are required in this choice. This is consistent with experiments in which a mutated molecule of CD4 (tailless), incapable of binding p56^{lck}, can rescue T helper development in a CD4^{-/-} mouse line. Therefore, in the context of thymic selection, the role of CD4 in the coreceptor-mediated TCR signaling is one of stabilization of the TCR-MHC interaction. In mice deficient for CD4 coreceptor expression, 90% of peripheral $\alpha\beta$ TCR⁺ T cells are CD8⁺. These CD4^{-/-} mice have been used to show that the human CD4 molecule can substitute for its murine counterpart. Interestingly, the requirement for CD4 in superantigen-mediated negative selection of specific V β seems to be differential and inversely proportional to the avidity of some V β for Mls. That is, Mls1^A-CD4^{-/-} animals, thymocytes expressing V β 6, V β 8.1 and V β 9 are deleted as in normal animals, while V β 7⁺ thymocytes are not, reflecting the low avidity of V β 7 for Mls1^A. These cells might require CD4 coreceptor-mediated stabilization of binding or signaling for clonal deletion. T helper activity and most class II-restricted T cell responses are also virtually absent in the periphery of these animals. For example, antibody titers are diminished 100-fold when these animals are immunized with T cell-dependent antigens. Moreover, these animals fail to mount an allo-response.

CD5 was initially detected as an alloantigen called Ly-1 on murine T cells and together with the alloantigen Ly-2,3 (now CD8) they were the first 'markers' to be used to identify functional T cell subpopulations. Ly-1 identified a helper T cell population while Ly-2,3 was present on a cytotoxic-suppressor subset. With more sensitive analysis it was shown that the Ly-2,3⁺ T cells also expressed low levels of surface Ly-1 in their membranes, thus indicating that the majority, if not all, T cells expressed Ly-1. A few years later, a pan-T cell marker of similar molecular mass was identified on human lymphocytes by a variety of monoclonal antibodies and termed CD5. Subsequent studies showed that this molecule was homologous at the DNA level with Ly-1.

Structure of the molecule

CD5 is a type 1 transmembrane glycoprotein with a molecular mass of 67 kDa. It comprises a single polypeptide of around 470 amino acids as deduced from the nucleotide sequence. The first 25 amino

acids form the signal peptide. The external portion of the molecule contains 22 cysteines. The outer of the three external domains shows the greatest homology with the immunoglobulin supergene family of molecules with an intrachain disulfide bridge. All three outer domains show homology with a protein, Pap D, which is a chaperone protein mediating assembly of P pili of *E. coli*. In addition, there is strong homology of the extracellular domain(s) with the scavenger receptor on macrophages. CD5 has a transmembrane sequence of 29 residues and an intracytoplasmic tail of 92 amino acids with four phosphorylation sites – consistent with the function of this molecule being one of signal transduction (see later). Approximately 25% of the CD5 molecule is composed of N- and O-linked oligosaccharides.

Cellular distribution of CD5

CD5 is expressed on the surface of all T cells bearing the $\alpha\beta$ heterodimer T cell receptor (around

50 000 molecules per cell) but is absent or at lower density on the $\gamma\delta$ T cell subset.

It is present but at lower density (2–10 000 molecules per cell) on a minor population of murine and human B cells. More sensitive techniques are therefore required to detect CD5 on B than on T cells. CD5⁺ B cells, now termed B1 cells, represent a significant proportion of murine thymic and peritoneal B cells. They are the first B cells to colonize lymphoid tissues during early development in humans and are present at very high frequency in the blood of newborns, diminishing through childhood, adulthood and up to old age. Interestingly, all B cells in mature rabbits are CD5 positive.

CD5 has been found on many murine B cell lymphomas, some human B cell lymphomas and on the majority of human chronic lymphocytic leukemia (CLL) cells.

Other cells which have been shown to express CD5 are endothelial cells of blood vessels in the pregnant sheep uterus but the significance of this isolated example of nonlymphoid cell expression of CD5 is at present unknown.

Ligands for CD5

To date, three ligands for CD5 have been identified: 1) CD72 on B cells (mouse and human) is thought to act as a costimulatory molecule during cognate interaction with T cells (see later); 2) immunoglobulin V_H α 2 framework sequences in the rabbit bind to CD5; and 3) a molecule of around 32 kDa on activated murine spleen cells binds to CD5. The significance of the latter two ligands is at present unclear but might be involved in selection processes.

Role of CD5 on T cells

As indicated above, CD5 is found on thymocytes and the majority of peripheral T cells. Increased expression of CD5 by a number of protein kinase C activators has suggested that this molecule is important in the activation process of T cells (and probably B1 cells). CD5 is associated with the TCR ζ chain and the cytoplasmic domain of CD5 is phosphorylated on tyrosines on activation via the TCR. This is thought to bind SH2 domain-containing proteins. Studies on peripheral T cell activation *in vitro* have shown a costimulatory role for CD5 on TCR-mediated proliferative responses. Thus, cross-linking of CD5 on T cells by monoclonal antibodies results in a rise in intracellular Ca²⁺ derived from an extracellular source (via Ca²⁺ channels) and generation of

cyclic GMP. Furthermore, solid-phase immobilization of CD5 antibodies alone provides a stimulus for interleukin 2 (IL-2) receptor induction and responsiveness to IL-2. It is thought that, along with other costimulatory interactions of molecules on T and B cells, CD5 on T cells binds to CD72 on B cells which enhances T cell and B cell activation. In contrast, in CD5 knockout mice, unlike peripheral T cells, thymocytes are hyper-responsive to stimulation through the TCR. In addition, selection of T cells expressing transgenic TCRs were abnormal in these mice indicating that CD5 plays a role as a negative regulator of TCR mediated activation during T cell development.

B cells and CD5

Unlike T cells, CD5 is present on only some B cells and there is now strong evidence that this is a marker which identifies a normal B cell subpopulation (B1 cells), the size of which is genetically regulated. This population is different in origin, and can be distinguished from, conventional B cells responsible for most of the antibodies specific for exogenous antigens. In mice, B1 cells are self-renewing.

Both murine and human studies have indicated that B1 cells have minimal mutation of their rearranged immunoglobulin genes. They are responsible for the production of polyreactive and autoreactive antibodies and give rise to the so-called 'natural antibodies' present in normal serum. In this regard, elevated levels of CD5⁺ B cells have been described in a plethora of autoimmune diseases in man including rheumatoid arthritis, primary Sjögren's syndrome, systemic lupus erythematosus, Graves' disease, diabetes and many more. The significance of this is at present unclear. The presence of CD5 on human CLL cells and the polyreactive nature of antibodies programmed by these cells indicates that these malignant B cell tumors, are derived from this particular B cell subpopulation.

It is likely that normal B1 cells can act as 'antigen-presenting cells', using their polyreactive receptors to take in antigens for processing and presentation with surface major histocompatibility complex (MHC) class II molecules.

Identification of CD5 as a lineage marker has recently been challenged in experiments with murine and human cells. Expression of CD5 can be induced on murine splenic B cells (mostly B2 cells) following activation. In humans, B cells activated by phorbol ester treatment express CD5, and IL-4 has been shown to downregulate this molecule on the surface of these cells.

Taking these data together, it is possible that classical B1 cells prominent in early life are antigen-presenting cells and are a separate lineage representing germline encoded antibodies, many of which are activated through recognition of self antigen *in vivo*. Other B cells (B2 cells) appear to be capable of being induced to express CD5. The function of CD5 on these two B cell types may be different. The function of CD5 molecules on B cells has recently been addressed and there is now substantial evidence for its role in regulating B cell activity. CD5 is part of the B cell receptor complex as shown by capping and co-capping studies. Cross-linking of CD5 on B cells by monoclonal antibodies has a profound effect on stimulation of B cells through the antigen-specific immunoglobulin M (IgM) receptor. In mice, stimulation of peritoneal B1 cells with anti-IgM results in apoptosis. This is inhibited in CD5-deficient (CD5 knockout) mice. Cross-linking of CD5 in normal wild-type mice rescues the cells from anti-IgM-induced apoptosis and leads to proliferation of these cells. A similar effect is seen with human tonsillar CD5⁺ B cells in the presence of IL-2. Direct stimulation of CD5 on human tonsillar B cells alone can also stimulate apoptosis but different biochemical pathways appear to be used compared with induction of apoptosis via anti-IgM. The physiological relevance of these latter observations is currently unknown.

Recent data have suggested that in mice, one of the signal transduction activators of transcription (STAT3) is constitutively activated in B1 cells but not in unmanipulated B2 cells. This may play a role in B cell antigen-specific signaling and its constitutive activation, associated with the intrinsic proliferative nature of this population.

CD5 as a target for therapy

Since CD5 is a pan-T cell marker it is used as a target for depletion of normal T cells in the clinical setting for transplantation and human therapy. It has an advantage over anti-CD3 treatment since it does not result in activation of cytokine production which gives rise to transient 'flu-like' symptoms after injection. Monoclonal antibodies coupled to ricin (immunotoxin) are used in the treatment, *ex vivo*, of allogeneic bone marrow for prevention of graft-versus-host disease following ablation therapy for transplantation. These antibodies have also been used successfully with additional therapy in the treatment of CLL tumors.

CD8

Georg F Weber and **Harvey Cantor**, Harvard Medical School and Laboratory of Immunopathology, Dana-Farber Cancer Institute, Boston, MA, USA

Definition of T cell subsets

CD8 represents the first cell surface glycoprotein used to define T cell subsets. Studies into the cellular basis of the immune response had shown that T lymphocytes mediated a wide variety of immunological functions. These cells generated cytotoxic responses to alloantigens, exerted helper and suppressor effects on the production of antibodies by B cells and initiated both delayed-type inflammatory responses and graft-versus-host responses. These findings could be explained by one of two alternative hypotheses. A single mature T lymphocyte, after activation by antigen, could give rise to cells capable of mediating the complete range of T cell responses. Alternatively, each T cell function might be mediated by a subset of T cells programmed during differentiation to express a limited range of immunological functions.

A direct approach to this question made use of alloantibodies that defined cell surface differentiation antigens, called Ly antigens, found on mouse thymocytes and a fraction of peripheral lymphocytes. Since these alloantigens had not yet been detected on the surface of nonlymphoid cells, it was hoped that they might represent components expressed exclusively on the surface of lymphocytes undergoing thymus-dependent differentiation. Lyt-2, since renamed CD8, and Lyt-3 represent cell surface antigens encoded by two closely linked genes. Lyt-2⁺3⁺ cells accounted for approximately half of peripheral T cells and included those cells required for generation of cytotoxic activity and excluded T cells that mediated helper activity. Additional studies of the major histocompatibility complex (MHC) specificity of CD8⁺ and CD8[−] subclasses of T cells revealed that thymus-dependent differentiation gave rise to at least two separate sublines of mature T cells. The CD8[−] subset was programmed to amplify a number of immune responses and was preferentially activated by class II MHC products in association with

antigenic peptides. The CD8⁺ subset was programmed for the development of cytotoxic T lymphocyte (CTL) activity and responded preferentially to class I MHC products in association with antigenic peptides. These studies showed that thymus-dependent differentiation resulted in two lineages of T cells, CD8⁺ and CD8[−], equipped to recognize and respond to products of the MHC that were foreign by virtue of polymorphic variation (alloantigen) or because they had been modified by association with nonself peptides. Selective engagement of either screening system by foreign or altered class I or class II MHC region products activated a series of immune reactions already programmed in one or another activated T cell subset.

Structure of CD8

CD8 exists as a disulfide-linked dimer of either α and β chain or two α chains. The crystal structure of the N-terminal 113 amino acids of human CD8 revealed homology to immunoglobulin (Ig) variable domains with nine β strands divided into two β sheets, one of four and the other of five strands. An Ig-like intersheet disulfide bridge from the B strand to the F strand is present in CD8 α . Another disulfide bond may be formed between cysteines in the B strand and the C strand. The hinge region connecting the amino-terminal Ig-like domain to the transmembrane segment consists of 50 residues in the α chain and 30 residues in the β chain, both of which are likely to be glycosylated and sialylated. The level of sialylation on the β chain hinge region varies with the activation state of the T cell and may have functional implications for CD8 (Figure 1).

Class I MHC recognition

It has become apparent that the CD8 molecule directly contributes to the development of cytotoxic activity by CD8⁺ cells. Antibodies to CD8 block the

Figure 1 Three-dimensional molecular model of the N-terminal region of a CD8 homodimer consisting of two α chains; (A) ribbon presentation, (B) stick presentation. The structural data for the N-terminal 113 amino acids are based on crystallography (protein data base: 1CD8). The three-dimensional model for each monomer was generated with RasMol version 2.5 (Roger Sayle, Greenford, Middlesex, UK), and the two monomers were combined as described (Leahy *et al.* (1992) *Cell* 68: 1145). The color coding represents groups; blue corresponds to the CDR1-like loop, light blue to the CDR2-like loop, and lime to the CDR3-like loop. The monomers are distinguished in brightness of color. (See also color Plate 10.)

generation and effector phases of the CTL response specific for class I MHC antigens without regard to function. Functional and cell-binding studies have shown that the ligands for the CD8 receptor are encoded by MHC class I genes. A role for CD8 in the interaction with class I molecules was demonstrated from the ability of CHO cells transfected with the

CD8 gene to form conjugates with class I-positive but not class I-negative cells. Similar to the interaction between CD4 and MHC class II, CD8 binds with weak affinity to MHC class I and contributes to cell adhesion. CDR-like loops (homologous to the complementarity-determining region 2 loop of antibodies) in the N-terminal end of CD8 α are the most likely binding site for MHC class I as judged by mutational analyses, crystal structure and orientation in the cell membrane. In addition, an A/B strand surface may interact with a region on the $\alpha 2$ domain of MHC class I. The primary binding site on MHC class I is the $\alpha 3$ loop, a nonpolymorphic region in the membrane proximal domain and distant to the antigen-binding cleft. Furthermore, the structures of CD8 and MHC class I make it possible that one CD8 dimer could simultaneously bind two MHC class I molecules.

Biochemistry and genetics

Lyt-2 and Lyt-3 (murine CD8) are both transmembrane glycoproteins which are encoded by two closely linked genes on murine chromosome 6. Except for a subset of natural killer cells, the expression of murine Lyt-2/3 appears to be restricted to T cells. The molecule is a 70 kDa homo- or heterodimer composed of two covalently linked chains: an α chain (32–38 kDa), which expresses epitopes detected by Lyt-2-specific antibodies, and a β chain (30–34 kDa), which expresses Lyt-3 epitopes. The Lyt-2 chain is the homolog of the CD8 chain in humans, which consists of homodimers and multimers of this chain. Recently, human CD8 β genes have been identified that encode a CD8 monomer corresponding to murine Lyt-3.

The Lyt-2 gene contains five exons. The first encodes a signal peptide and an N-terminal region which shows close homology with IgV κ light chain regions, including a cysteine-mediated intrachain disulfide bond. Exons 2–5 encode the spacer region, the transmembrane region and two cytoplasmic regions, C1 and C2, respectively. Although there is only a single Lyt-2 gene segment there are two types of Lyt-2 chains, α and α' , of slightly different size. The 34 kDa α' chain, found only in mice and expressed preferentially in the thymus, is a truncated form of the α chain resulting from alternative splicing of exons encoding the C-terminal cytoplasmic domain including the p56^{lck} binding site.

There is uneven homology between human and murine CD8 molecules. Human CD8 α and β chains are encoded on chromosome 2p12. The most substantial degree of genetic conservation is found in the transmembrane and cytoplasmic domains, while the

least is in the external V gene-like domain. Since there is 70% identity of the class I MHC external domain residues between mouse and human, this degree of divergence in the putative binding regions of CD8 is somewhat surprising. On the other hand, conservation of the C-terminal domain may reflect a requirement for this region to interact with intracellular T cell proteins involved in transmembrane signaling. A comparison of rodent CD8 chains with the α and β chains of the T cell receptor (TCR) suggests evolution of these three receptor genes from a common ancestor. Divergence between them may be reflected in the acquisition of intervening sequences between V and J by the TCR genes, resulting eventually in the capacity to rearrange multiple V genes during development. The CD8 gene has lost regions encoding C-region domains but, like TCR, has acquired the capacity to recognize MHC molecules at some point in evolution (Figure 2).

T cell activation

Studies have shown that CD8 may function as a coreceptor with the α/β TCR in recognition of adjacent epitopes on the same class I molecule. These findings support the concept that T cell activation involves formation of a ternary complex composed of CD8 and TCR on the T cell and class I MHC molecules on the target cell. Indeed, ligation of CD8 with the TCR complex elicits much more vigorous T cell responses than ligation of either receptor molecule alone, indicating that CD8 plays a decisive role in augmenting TCR-dependent activation, either by increasing the avidity of binding to MHC class I or

by amplification of signal transduction. High-avidity interaction between T cells and antigen-presenting cells is heavily dependent on CD8 expression, which is more important for primary proliferative responses than for CTL activity. While stimulation of T cells by anti-TCR antibodies results in coordinate localization of TCR and CD8, it is not yet clear whether the TCR α/β chain directly contacts the CD8 molecule in the lipid bilayer of a cell membrane. However, the ability of the two cell surface molecules to interact with distinct but adjacent regions of class I MHC products places CD8 and the TCR in close proximity to one another.

A potential molecular basis for the role of CD8 in T cell activation comes from studies showing that CD8 is closely associated with the tyrosine kinase p56^{lck}, an src-related tyrosine kinase expressed mainly in T lymphocytes. p56^{lck} is a cytoplasmic protein that, unlike other growth factor receptors, is found on the inner leaflet of the plasma membrane where it associates with a highly conserved cytoplasmic domain of CD8. Site-directed mutagenesis of CD8 defines a motif of CD8 α which may bind to the N-terminal region of p56^{lck}: ++-x-cys-x-cys-(pro) where x denotes a nonconserved residue and + a basic residue. It is currently thought that engagement of CD8 leads to enhanced activity of the associated p56^{lck} enzyme which phosphorylates the ζ chain of the CD3 complex leading to signal transduction. In mature T cells, CD4 and CD8 may associate with equal amounts of p56^{lck}; however, kinase activity after cross-linking of CD8 is much lower than after cross-linking of CD4. On the other hand, protein kinase C appears to be activated much more strongly after ligation of CD8 than after ligation of CD4. The cytoplasmic segment of CD8 α also has two serine residues which are likely to be phosphorylated in signaling. T cells with targeted mutations of the cytoplasmic serine residues are insignificantly impaired in their response to antigen, whereas cells with substitutions in both cytoplasmic cysteine residues display deficient responses. Surprisingly, transgenic mice whose CD8 lacks the p56^{lck} binding site show no impairment of T cell function.

Figure 2 Exon-intron organization of the human CD8 genes. The CD8 α gene is comprised of six exons which span about 8 kb. There are two genes encoding CD8 β , CD8B-1 contains eight exons and is spread over approximately 48 kb, whereas the CD8B-2 gene consists of six exons and has a length of 20 kb. L = leader peptide, V = IgV-like sequence, M = membrane proximal region, TM = transmembrane domain, C = cytoplasmic domains.

T cell selection

The ability to trace T cell clones according to their TCR α/β chain expression has led to the demonstration of MHC-dependent negative and positive selection in the thymus. These studies also provide strong evidence for the involvement of the CD8 molecule in class I-mediated positive selection. Although the precise role of CD8 in this process is not known, there is good evidence that the generation of single-

positive CD8 cells from double-positive ($CD4^+8^+$) precursors in the thymus is associated with class I MHC recognition. Possibly, coordinate ligation of TCR and CD8 with class I MHC at the $CD4^+8^+$ precursor stage induces the cell to shut off CD4 expression. Alternatively, CD4 or CD8 might be eliminated on a random basis at the double-positive stage, allowing the formation of single-positive CD8 cells or CD4 cells. The former $CD8^+4^-$ population would be equipped to be selected by class I MHC, while the latter ($CD8^-4^+$) cells would display a TCR specific for class II and would die in the thymus. CD8 may also contribute to negative selection, as highly elevated levels of $CD8\alpha$ block thymocyte maturation. Immature $CD4^+CD8^+$ thymocytes express CD8 at levels fourfold higher than CD4; nevertheless, activation of $p56^{lck}$ is mostly seen after ligation of CD4 but not CD8, as a minority of surface CD8 molecules are associated with $p56^{lck}$. It has been shown that negative selection does not require increased CD8-dependent signaling through $p56^{lck}$. A critical question that remains to be answered involves the role of CD8 in the differentiation of cytotoxic cells. Possibly, a signal mediated by CD8 results in the differentiation of a thymic precursor cell to a prekiller and killer cell. An alternative explanation is that CD8 represents part of the mature cytolytic cell program. In either case, a critical feature of CD8 expression is restriction of cytolytic responses to T cells that recognize class I but not class II MHC products. This feature of the CD8 genetic program may prevent cytolytic cells from reacting to and eliminating class II-bearing B cells and macrophages that display relevant peptide antigens.

Analysis of CD8 by gene-targeting techniques

Models with manipulated CD8 genes have become available. Disruption of the $CD8\alpha$ gene prevents expression of CD8 protein on the cell surface and impedes generation of cells which express receptors specific for MHC class I. Disruption of the $CD8\beta$ gene, or removal of its cytoplasmic tail, has a less dramatic effect on MHC class I restricted cells. Mutant mice contain 20–30% of the normal number

of CD8 cells and those may have a restricted set of TCRs. These results are similar to the effects of eliminating the CD8 ligand: a deficiency of MHC class I gene products also prevents maturation of $CD4^+8^+$ cells. Introduction of a CD8 transgene with a mutated binding site for $p56^{lck}$ into $CD8\alpha^{-/-}$ mice leads to reduction of mature CD8 cells by half but no apparent restrictions of the TCR repertoire. In contrast, introduction of a tailless $CD8\alpha$ transgene into $CD8^{-/-}$ mice leads to a more dramatic reduction in CD8 cell numbers, reduced capacity to mount cytotoxic T lymphocyte responses, and restrictions in the TCR repertoire.

CD22 expression and cDNA cloning

CD22 is a B cell lineage, restricted cell surface phosphoglycoprotein of 130–150 kDa which demonstrates a unique developmental pattern of expression closely paralleling that of immunoglobulin D (IgD). Cytoplasmic expression of CD22 can be detected in pro-B and pre-B cells, whereas surface expression is first identified in immature B cells. B cell activation results in a transient increase in surface CD22 expression, which is followed by progressive down-regulation as activated B cells differentiate into plasma cells.

Two cDNA clones encoding human CD22 have been isolated and shown to predict an integral membrane polypeptide and a member of the Ig superfamily. The smaller isoform, CD22 α , possesses an extracellular domain composed of five Ig-like subdomains, while the larger isoform, CD22 β , is identical to CD22 α with the exception of two additional Ig-like extracellular subdomains (subdomains 3 and 4) positioned between subdomains 2 and 3 of the smaller isoform. The predominant isoform of human CD22 expressed in B cells is CD22 β and is henceforth called CD22 unless otherwise specified. A murine CD22 cDNA clone has been isolated and displays 62% amino acid identity to the human form, with the closest relatedness being located between the seventh Ig domain and the cytoplasmic tail, and the greatest divergence observed within Ig domains 1 and 2. The extracellular domains of CD22 are highly related to several known adhesion molecules, which include myelin-associated glycoprotein (MAG), Schwann cell myelin protein (SMP), CD33, sialoadhesin, neural cell adhesion molecule (NCAM), and the vascular adhesion molecule VCAM/InCAM110. Interestingly, the first Ig-like domain of CD22, like CD33, MAG, SMP and sialoadhesin, is a V-set domain which contains an unusual intradomain disulfide bond between the predicted B and E β strands rather than the B and F β strands ordinarily found in immunoglobulins.

B cell adhesion molecule CD22 is a sialic acid-binding lectin

COS cells expressing both human CD22 isoforms promote sialic acid-dependent leukocyte rosetting,

but transfectants expressing CD22 β promote leukocyte rosetting more strongly than COS cells expressing CD22 α . The sialic acid binding domain of CD22 has been demonstrated to be situated on the GFCC'C' β sheet of the V-set Ig domain centered on an arginine residue in the F strand. Furthermore, the second N-linked glycosylation site within the V-set Ig domain of CD22 has been demonstrated to play an important role in the regulation of CD22-mediated adhesion. While the binding domain of CD22 is localized to the first Ig-like domain, the second and third Ig-like domains as well as the second N-linked glycosylation site, play an important role in generating the optimal binding conformation.

Several studies using a soluble recombinant CD22-Ig fusion protein, CD22Rg, have shown that CD22 binds a variety of cell surface and soluble sialoglycoproteins and that the observed adhesion is dependent upon the presence of ligand-associated N-linked oligosaccharides containing α 2,6-linked sialic acid. The role of sialic acid in CD22 recognition is further supported by the observation that mild periodate oxidation of B and T cells, which selectively removes the C-7–C-9 exocyclic side-chain of sialic acid, results in the abrogation of CD22-mediated binding. The minimal oligosaccharide motif specifically recognized by CD22 is Neu5Ac α 2–6Gal β 1–4Glc(NAc). The apparent affinity of this interaction is low ($K_d \sim 30 \mu\text{M}$), suggesting that in common with most lectins the functional avidity of CD22 may be attained through multivalent binding. Further detailed analysis of N-linked oligosaccharides isolated from CD22 glycoprotein ligands has demonstrated that high-affinity recognition by CD22 is determined by the number of sialic acid residues associated with a glycoprotein ligand and by appropriate sialic acid presentation by the underlying ligand polypeptide backbone. These observations demonstrate that although CD22 is structurally related to the Ig superfamily of adhesion molecules, it has the functional properties of a sialic acid-binding lectin. The structurally related molecules CD33, MAG, SMP and sialoadhesin have been demonstrated to mediate α 2,3-linked sialic acid-dependent adhesion and, together with CD22, constitute a family of mammalian lectins, designated I-type lectins.

Regulation of CD22-mediated adhesion

CD22-expressing COS cells adhere to multiple subsets of leukocytes *in vitro*, yet CD22-bearing B cells do not demonstrate appreciable cell-cell adhesion *in vivo*. This suggests that B cells which constitutively express CD22 might possess regulatory mechanisms to avert undesired CD22-mediated aggregation. Interestingly, CD22 expressed in B cells possesses N-linked oligosaccharides that are sialylated exclusively in an α 2,6 linkage. Since α 2,6-linked sialic acid provides a natural CD22 ligand, this observation raises the possibility that α 2,6-linked sialic acid on CD22 itself might play a role in regulating CD22-ligand interactions. Recent studies have shown that α 2,6-specific sialylation of CD22 itself abrogates CD22-mediated adhesion. Additional studies *in vivo* have demonstrated that regulation of CD22-mediated adhesion may also occur at the level of the glycoprotein ligands. More specifically, 9-O-acetylation of the sialic acid side-chain of splenic, thymic and lymph node lymphocytes and macrophages has been demonstrated to negatively regulate CD22-mediated adhesion. Thus, regulation of CD22-mediated adhesion occurs at the level of reciprocal α 2,6 sialylation and sialic acid side-chain modification of both receptor and ligand. CD22 is the first known example of an Ig superfamily member whose function is under the control of two specific glycosyltransferases, α 2,6 sialyltransferase and O-acetyltransferase.

Role of CD22 in lymphocyte signal transduction

Multiple T and B cell surface glycoproteins have been immunoprecipitated using a soluble recombinant CD22-Ig fusion protein, CD22Rg. Several of these putative T and B cell ligands appear to have an identical molecular mass, and may represent the same polypeptides expressed on both T and B cells. The first of the CD22 T cell ligands to be identified was CD45. Subsequent *in vitro* experiments demonstrated that cross-linking of CD3 and CD22 T cell ligands with anti-CD3 monoclonal antibody (mAb) and CD22Rg on the surface of the T cell line CEM results in the inhibition of calcium flux and tyrosine phosphorylation of phospholipase C γ 1 (PLC γ 1) generated by cross-linking CD3 alone. However, the presence of multiple unknown CD22-binding glycoproteins on the surface of T cells, in addition to CD45, precluded the conclusion that the observed modulation of early T cell activation events was due exclusively to CD22-CD45 interactions. Through the use of several Jurkat cell lines, including a CD45-

deficient variant which was reconstituted with a recombinant fusion protein composed of the intracellular domain of CD45 and the extracellular and transmembrane domains of major histocompatibility complex (MHC) class I molecule HLA-A2, it was demonstrated that a direct physical interaction between CD22 and CD45 resulted in modulation of early signal transduction events. These experiments suggest that the interaction of CD22 on the surface of B cells with CD45 on adjacent T cells may play a role in regulating an immune response during T cell-B cell interactions.

The pattern of CD22 cell surface expression, coinciding with the acquisition of B cell responsiveness to antigen, suggests that CD22 may also play a role in early B cell activation events. Two early studies supported this notion. First, cross-linking of surface CD22 with anti-CD22 mAbs resulted in augmentation of anti-IgM-induced B cell activation signals. Second, anti-Ig responsiveness was demonstrated to be restricted to B cells which express surface CD22. Subsequent work has further supported the notion that CD22 plays a role in B cell signal transduction. CD22 has been demonstrated to be associated with surface Ig (sIg) and to be rapidly phosphorylated upon cross-linking of sIg. Furthermore, these phosphorylated intracellular tyrosine residues have been demonstrated to be arranged in one or perhaps two intracellular tyrosine-based activation motifs (ITAMs), one of which associates with p72^{syk}, p53/56^{lyn} and phosphatidylinositol 3-kinase during B cell activation. Most recently, intracellular tyrosine phosphorylation of CD22 has been shown to bind and activate protein tyrosine phosphatase 1-C (PTP1-C), which negatively regulates signaling through sIg. This suggests that ligation of sIg induces tyrosine phosphorylation of CD22, which in turn localizes and activates PTP1-C at the intracellular site of the signaling complex and thereby results in an inhibitory feedback effect on the activation of B cells. Additional experiments have shown that engagement and sequestration of CD22 from sIg with anti-CD22 mAb-coated protein A-sepharose lowered the threshold of B cell activation in a phosphorylation-dependent manner. Thus, overall these studies suggest that the absence or presence of CD22 in the sIg complex may serve to upregulate or downregulate B cell activation, respectively.

The functional relationship between the extracellular and the intracellular domains of CD22 is relatively unexplored; however, at least one line of evidence suggests that engagement of the extracellular domain of CD22 may, in turn, influence the function of the intracellular domain. Previous studies with the CD22 mAbs HD6 and HD39 have shown

that these antibodies could costimulate B cell proliferation with anti-IgM, but they were unable to directly stimulate B cell proliferation. Engagement of CD22 with the anti-CD22 mAb, HB22.23, which blocks the binding of CD22 to its ligands, results in rapid phosphorylation of CD22, increased association with Src and non-Src family kinases, and proliferation of B cells. These results taken together suggest that engagement of different epitopes of the extracellular domain of CD22 has different functional sequelae. It is rather interesting to note that the anti-CD22 mAb which could stimulate B cells directly was also an antibody which blocks the interaction of CD22 with its ligands; this raises the possibility that this particular mAb may recognize the same structural element which is required for CD22-mediated adhesion. If this is in fact the case, then engagement of CD22 by one of its ligands may result in direct modulation of B cell signal transduction events independent of sIg.

CD28

Jeffrey A Ledbetter and **Peter S Linsley**, Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, Washington, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

CD28 is a receptor on T cells that is activated by engagement with ligands CD80 (B7-1) and CD86 (B7-2) that are expressed on the surface of activated antigen-presenting cells (APCs). CD28 delivers signals to the T cell that increase expression of the high-affinity interleukin 2 (IL-2) receptor (CD25) and enhance the synthesis of multiple cytokines, including IL-2. Thus CD28 regulates T cell responsiveness to antigen during T cell contact with APCs. CD28 is referred to as a costimulatory receptor because the signals it provides are synergistic with signals provided by the T cell antigen receptor (TCR/CD3) in driving T cell activation and proliferation. In the absence of a signal from TCR/CD3, signals from CD28 can stimulate only minimal proliferation of T cells, and may result in T cell unresponsiveness. Although CD28 and TCR/CD3 work together, CD28 signals are at least partly independent of TCR/CD3, as, unlike TCR/CD3, CD28 signals are resistant to inhibition by cyclosporine.

CD28 Structure and expression

CD28 was first detected and characterized with a monoclonal antibody (mAb) (9.3) made by Paul Martin and John Hansen at the Fred Hutchinson Cancer Research Center in 1981. Studies with this mAb showed that CD28 is a differentiation antigen expressed on thymocytes and most mature T cells, including all CD4 T cells and CD8 T cells with cytolytic activity. A subpopulation of CD8 T cells with suppressor activity are CD28 negative. The CD28 molecule was shown to be a homodimeric glycoprotein composed of a disulfide-bonded 44 kDa subunit. The cloning and expression of a CD28 cDNA by Aruffo and Seed showed that each CD28 monomer contains 134 extracellular amino acids with a single transmembrane domain and a short cytoplasmic tail. The extracellular domain of CD28 shows homology with immunoglobulin variable region domains. The CD28 gene contains four exons, with each exon defining a functional domain of the protein. CD28 shares amino acid sequence homology with CTLA-4, a receptor expressed by activated T cells. CD28 and CTLA-4 genes are closely linked on human chromosome 2, bands q33-q34 (Figure 1).

CD28 Receptor function

The potent costimulatory activity of anti-CD28 mAbs was first recognized by Gmunder and Lesslauer and was later confirmed and studied by many others. Identification of CD80 and CD86 molecules as CD28 ligands has allowed a comparison of CD28 signaling through anti-CD28 mAbs versus the natural ligands. These studies show that CD28 clustering on the cell surface during cell-cell adhesion results in optimal stimulation, whereas soluble CD80-Ig or CD86-Ig fusion proteins are not effective. CD28 mAbs have activity in solution when they are bivalent or multivalent, but are less effective than CD80- or CD86-positive cells in activating the CD28 receptor. Optimal stimulation of the CD28 receptor therefore requires a high degree of receptor cross-linking or oligomerization.

CD28 signals depend on the activation of intracellular protein tyrosine kinases, including *lck* and *itk*, resulting in direct phosphorylation of CD28 on tyrosine residues. After activation, CD28 associates with phosphatidylinositol 3-kinase (PI3K) by an SH₂ interaction with phosphorylated Tyr170. However, the association with PI3K is not essential for CD28 costimulatory function, and Tyr188 plays a more important role. However, it is not yet clear how the CD28 cytoplasmic tail delivers costimulatory signals.

CD28-deficient mice have been generated and found to have an impaired immune system, with reduced responses to T cell mitogens and reduced ability to mount antibody responses to T-dependent antigens. In contrast, CTLA-4 deficient mice die at an early age of lymphoproliferative disease, demonstrating that CTLA-4 delivers inhibitory signals for T cell activation. CTLA-4 has been reported to associate with a tyrosine phosphatase, SYP, that is thought to inhibit the activation of tyrosine kinases or tyrosine kinase substrates during CD28 cross-linking.

CTLA4-Ig

Soluble CD28-Ig and CTLA-4-Ig fusion proteins have been expressed and found to bind their shared ligands with different affinities. CTLA-4-Ig binds more than 100-fold better than CD28-Ig to both CD80 and CD86, and CTLA-4-Ig inhibits the ability of CD80 or CD86 to stimulate CD28 responses.

Figure 1 The CD28 receptor system. CD28 and CTLA-4 are stimulated by CD80 and CD86 ligands on activated APCs. Signals from CD28 are required for T cell activation and cytokine secretion, while signals from CTLA-4 inhibit T cell activation.

CTLA-4-Ig has been tested in numerous animal models of autoimmune disease and transplantation, and is currently in a phase I clinical trial in patients with refractory psoriasis. CTLA-4-Ig offers significant promise as a selective, nontoxic molecule for improved immunosuppressive therapy.

CD40 AND ITS LIGAND

Jacques Banchereau, Baylor Institute of Immunology Research, Dallas, Texas, USA

The CD40 antigen was identified in the mid-1980s from monoclonal antibodies that react with carcinomas and B cells and show costimulatory effects for B lymphocyte proliferation. In the early 1990s, the CD40 ligand (CD40-L) was identified on activated T cells and its genetic alteration was found to lead to the X-linked immunodeficiency referred to as the hyper IgM syndrome.

Structure and expression of CD40 and its ligand

The CD40 antigen, a 45–50 kDa glycoprotein of 277 amino acids, is a member of the tumor necrosis factor receptor family. The 193 amino acid extracellular domain is composed of four imperfect repeats of approximately 40 residues, anchored by a superimposable pattern of six cysteines. This organization is found in the other members of the superfamily including: the p75 low-affinity nerve growth factor receptor; the p55/CD120a and p75/CD120b receptors for tumor necrosis factor; the receptor (TNF-R_{rp}) for the lymphotoxin α /lymphotoxin β membrane complex; CD27 and CD30; OX40; 4-1-BB/ILA; Fas/CD95; and two viral homologs of the TNF receptors. The X-ray crystal structure of the complex formed by soluble binding domains of p55 TNF-R and a lymphotoxin α trimer suggests that CD40 looks like a slightly bent rod. Three CD40 subunits are likely to engage the CD40-L trimer and scrupulously avoid contact between each other. The mouse CD40 gene, composed of nine exons that span 16.3 kb of genomic DNA, is located on the distal region of chromosome 2, which is syntenic to human chromosome 20q11–q13, where the human CD40 gene is located. CD40 is expressed by multiple cell types. In the hematopoietic system, it is expressed on CD34⁺ hematopoietic progenitors, B cell progenitors, mature B lymphocytes, plasma cells, monocytes, dendritic cells and on some T lymphocytes. CD40 is also expressed on nonhematopoietic cells such as endothelial cells, fibroblasts and epithelial cells. In 1992, expression cloning using a CD40-Fc fusion protein allowed the isolation of a CD40-L from activated T cells. The human CD40-L is a polypeptide of 261 amino acids, including a 215 amino acid extracellular domain with five cysteines. CD40-L is a member of the tumor necrosis factor (TNF) family

that includes TNF α , LT α , LT β , CD27-L/CD70, CD30-L, 4-1BB-L, OX40-L, Fas-L and TRAIL. The gene for CD40-L is located on the X-chromosome position q26.3–q23.1. It spans over 12–13 kb and consists of five exons. CD40-L is readily expressed on CD4⁺ and CD8⁺ T cells after activation through pathways that are inhibited by cyclosporine. Basophils, eosinophils and activated B lymphocytes have also been reported as expressing CD40-L.

CD40 signal transduction

While the TNF-R family members display structural homologies in their extracellular ligand-binding domains, no obvious homologies can be detected in their intracellular domains. In particular, CD40 has no kinase domain and no known consensus sequence for binding to kinases. Yet, CD40 ligation activates protein-tyrosine kinases, including *lyn* and *syk* and induces the tyrosine phosphorylation of multiple substrates including phosphatidylinositol 3-kinase and phospholipase C γ 2. The phosphorylation of the latter is consistent with the anti-CD40 induced IP₃ production. The inhibitory effects of protein-tyrosine kinase inhibitors and of CD45 cross-linking demonstrate the functional relevance of the CD40-induced tyrosine phosphorylation. CD40 ligation also appears to activate the serine-threonine protein kinases and, most particularly, the stress-activated protein kinases (SAPK, also known as JNK for c-jun NH₂-terminal kinase). Finally, these different activation pathways result in the activation of various transcription factors including NF- κ B, NF- κ B-like molecules (such as p50, p65 (rel A), c-Rel), c-jun and NF-AT.

Through their intracytoplasmic domains, the members of the TNF-R family bind to a family of intracellular molecules, the TRAF proteins for (TNF-R)-associated factors. CRAF₁/TRAF₃, a 62 kDa intracellular protein, binds to the cytoplasmic domain of CD40 and to the EBV (Epstein-Barr virus)-transforming gene product LMP-1 (latent infection membrane protein 1) but not to TNF-R_I, TNF-R_{II} or Fas. CRAF₁/TRAF₃ appears to be essential for CD40 signaling inasmuch as a mutant CD40 with a point mutation Thr-234 to Ala does not bind CRAF₁/TRAF₃ and is functionally inactive. In addition to recruiting TRAF₃, CD40 utilized TRAF₂,

a 56 kDa intracellular protein that is also used by the 75 kDa TNF-R.

Functions of CD40 *in vitro* (Figure 1)

B lymphocytes

CD40 ligation activates resting B cells as shown by increase in size and expression of new surface molecules involved in homotypic and heterotypic aggregation (CD23, VLA-4), T cell costimulation (CD80/CD86) as well as cell death (Fas). Importantly, dual triggering of resting B lymphocytes through their CD40 and antigen receptor induces a phenotype characteristic of cells from germinal centers, the anatomical site where B cells become memory cells. Furthermore, CD40-activated B cells secrete a panel of cytokines which may act as autocrine and paracrine growth and differentiation factors. CD40-activated B cells also enter into proliferation which is further stimulated by addition of cytokines such as interleukin 4 (IL-4), IL-13 or IL-10 and their combination. Cytokines can also induce CD40-activated B cells to secrete immunoglobulins, with IL-10 inducing the secretion of large quantities of immunoglobulins (Igs) as a consequence of

induced plasma cell differentiation. In addition to being a differentiation factor, IL-10 acts as a factor inducing switch towards IgG1 and IgG3, as well as IgA when combined with transforming growth factor β (TGF β). IL-4/IL-13 induce CD40-activated B cells to switch towards IgG4 and IgE. Prolonged triggering of CD40 skews the maturation of B cells into memory cells, while interruption of CD40 signaling allows plasma cell differentiation.

While progenitor B lymphocytes proliferate in response to CD40 engagement, plasma cells appear unresponsive. Regarding B cell malignancies, chronic lymphocytic leukemias, acute lymphoblastic leukemias, B cell lymphomas, hairy cell leukemias and multiple myelomas proliferate in response to CD40 engagement. In contrast, CD40 ligation appears to inhibit the proliferation of diffuse B cell lymphomas, thus illustrating a possible negative role of CD40 on cell proliferation.

Monocytes and dendritic cells

The low spontaneous expression of CD40 on monocytes can be upregulated by cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3 and interferon γ (IFN γ). In contrast,

Figure 1 Functional consequences of CD40 triggering on different cell types. Activation includes increase in cell size and alteration of phenotype. (Reproduced with permission from van Kooten C and Banchereau J (1996) CD40 and its ligand. *Advances in Immunology* 61: 1–77.)

CD40 is expressed at high levels on dendritic cells isolated from different tissues or generated *in vitro* by culturing hematopoietic progenitors. CD40 ligation of monocytes and dendritic cells results in the secretion of multiple cytokines, including IL-1, IL-6, IL-8, IL-10, IL-12, TNF α and MiP1 α . Importantly, the secretion of IL-12 allows a skewing of T cell maturation towards the T_H1 pathway. CD40 ligation considerably alters the phenotype of these antigen-presenting cells (APCs) by upregulating the expression of costimulatory molecules such as CD54 (ICAM-1), CD58(LFA-3), CD80(B7-1), CD86(B7-2). Interrupting CD40/CD40-L interactions during T cell/dendritic cell cocultures results in reduced T cell proliferation. This observation is likely to be the consequence of both altered CD40 signaling to the APCs (reduced expression of costimulatory membrane molecules and cytokines) and altered CD40-L signaling to the T cells. Indeed, it was clearly demonstrated that CD40-L-dependent activation of T cells occurs through signaling of CD40 in the antigen-presenting cell to enhance requisite costimulatory pathways including B7. CD40 ligation turns on monocyte tumoricidal activity as well as nitric oxide synthesis. In response to CD40 ligation, CD34⁺ hematopoietic progenitors proliferate and differentiate into cells with prominent dendritic cell attributes. Such dendritic cells are not only capable of inducing primary T cell activation but also interact with activated B cells enhancing their proliferation and differentiation.

Endothelial cells, epithelial cells and fibroblasts

Immunohistology performed on various tissue sections shows that CD40-L-specific antibodies stain vascular endothelium, epidermal basal membrane, scattered fibroblasts, thymic epithelium and follicular dendritic cells. Consistently, primary lines of endothelial cells, thymic and kidney tubular epithelial cells, keratinocytes, skin and synovial fibroblasts as well as follicular dendritic cells express CD40 at relatively low density. Yet, these adherent cells express a functional CD40 whose ligation induces phenotypic alterations, cytokine secretion as well as stimulation or inhibition of proliferation. In particular, endothelial cells display marked upregulation of CD54(ICAM-1), CD106(VCAM-1) and CD62E(E-selectin), thus resulting in increased ability to bind leukocytes. Interestingly, while fibroblasts and follicular dendritic cell lines are induced to proliferate following CD40 ligation, keratinocyte lines cease proliferating to terminally differentiate.

***In vivo* functions of CD40(CD40-L) interactions**

Hyper IgM syndrome in humans

The first demonstration of the critical role of CD40(CD40-L) interactions *in vivo* came from the discovery that the hyper IgM syndrome, an X-linked immunodeficiency, is due to a genetic alteration of the CD40-L. This disease is characterized by a severe impairment of T cell dependent antibody responses with no B cell memory, no circulating IgG, IgA and IgE and no somatic hypermutation, as a consequence of the lack of germinal centers within secondary lymphoid organs. Enhanced susceptibility of patients to opportunistic infections, such as *Pneumocystis carinii* pneumonia and *Cryptosporidium* diarrhea, also indicates a role for CD40-CD40-L interactions in cell-mediated immune responses. Interruption of CD40 (CD40-L) interactions *in vivo* in mice impairs B cell memory as well as T cell priming. Initial experiments performed with antagonists to CD40(CD40-L) interactions, such as antibodies to CD40-L or CD40-Fc fusion proteins, demonstrated impairment of B cell memory. The generation of CD40 and CD40-L knockout (KO) mice confirmed and further extended these observations and revealed a phenotype comparable to that of the patients suffering from the hyper IgM syndrome. In particular, these mice display decreased IgM responses to thymus-dependent antigens, no antigen-specific IgG1, IgA and IgE and no germinal centers but normal T and B lymphocyte numbers. As expected, these mice respond normally to thymus-independent antigens with increased IgM and IgG3 levels. CD40-L KO mice display a considerable impairment of antigen-specific T cell priming and appear particularly susceptible to *Leishmania* infection. This is the result of a defective T_H1 response which is related to an impaired production of IL-12 by antigen-presenting cells. As observed in patients, CD40 KO mice show decreased reactive granulopoiesis in response to infections. Studies with a CD40-Fc fusion protein have highlighted the important role of T cell signaling through CD40 ligand in the development of helper function. In particular, administration of soluble CD40 *in vivo* to CD40 KO mice initiates germinal center formation, and T cells primed in the absence of CD40 are unable to help normal B cells to class switch and to form germinal centers. In this context, ligating CD40 ligand of human activated T cells considerably enhances their production of IL-4.

Interruption of CD40-CD40-L interactions as a treatment of autoimmunity

Administration of antibodies to CD40-L has been

shown to prevent the establishment of autoimmune symptoms in various murine models including: 1) collagen type II-induced arthritis, a model for human rheumatoid arthritis; 2) lupus nephritis in lupus-prone mice that represent models of systemic lupus erythematosus; 3) proteolipoprotein-induced experimental encephalomyelitis, a model of human multiple sclerosis. Importantly, in this last case, the antibody could induce a substantial reduction of the disease even when administered after onset. Consistently, activated helper T cells expressing CD40-L surface protein are detected in multiple sclerosis patient brain sections where CD40-bearing APCs can be found.

Interruption of CD40-CD40-L interactions as a way of inducing transplantation tolerance

Administration of CD40-L-specific antibodies prevents the development of graft-versus-host disease (GVHD) that occurs as a major complication of allogeneic bone marrow transplantation. This treatment affects both the acute GVHD, essentially mediated by cytotoxic T cells, and the chronic GVHD, mainly due to the polyclonal B cell activation and the production of self reactive antibodies. Antibodies against CD40-L markedly prolong the survival of cardiac allografts in both naive and sensitized hosts when administered at the time of transplantation. Finally, a combination of allogeneic B cells and CD40-L-specific antibody considerably decreases host reactivity of both CD4⁺ and CD8⁺ T lymphocytes, thereby allowing efficient transplantation of allogeneic pancreatic β islet cells. The addition of CD40-L-specific antibody appears to considerably enhance the tolerogenic effect of B cells.

Thus, multiple pathologic states appear to be improved by interruption of CD40-CD40-L interactions. While this is presently accomplished by preventing the association of the receptor with its ligand, using antibodies or soluble receptor, small synthetic chemical agents preventing this interaction may eventually be identified. However, it is likely that pharmacologic agents may be found that will

block the intracellular pathways turned on after ligation of either CD40 or CD40-L.

CD44

David Naor, The Lautenberg Center for General and Tumor Immunology, The Hebrew University–Hadassah Medical School, Jerusalem, Israel
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

CD44 is a ubiquitous multistructural and multifunctional cell surface glycoprotein involved in adhesive cell–cell and cell–matrix interactions, as well as in cell migration and cell homing. Its principal ligand is hyaluronic acid (HA, hyaluronate, hyaluronan). The glycoprotein was accorded various functional names which merged to an established single name only after molecular sequencing. The CD44 cluster assigned by the Third International Workshop on Leukocyte Typing includes the following earlier synonyms: GP90^{Hermes}, extracellular matrix receptor III (ECMR^{III}), homing cell adhesion molecule (HCAM), phagocytic glycoprotein 1 (Pgp-1), glycoprotein 85 (gp85), Ly-24, hyaluronate receptor, HUTCH-1 and ln (Lu)-related-p80 glycoprotein.

Structure

CD44 is encoded by a single gene located on human chromosome 11 and mouse chromosome 2. The genomic organization of the CD44 gene involves 20 exons in both mouse and humans (Figure 1b). The first five exons coding for the extracellular domain are constant, whereas the next ten exons are subjected to differential alternative splicing, resulting in the generation of the variable region. Note that exon 6 (or V1) is not expressed in humans. Constant exons 16 and 17, together with part of exon 15, encode the membrane-proximal region; constant exon 18 encodes the transmembrane domain. Differential utilization of exons 19 and 20 generates the short version (3 amino acids) and the long version (70 amino acids) of the cytoplasmic tail, respectively.

Standard CD44 (CD44s), which lacks the entire variable region (Figure 1c), is preferentially expressed on hematopoietic cells, and is therefore also designated CD44H. Northern blot analysis of RNA isolated from CD44 of different hematopoietic cells revealed three major transcripts in humans (~1.6, 2.2 and 4.8 kb) and mice (~1.6, 3.3 and 4.6 kb). Human CD44s mRNA is translated into 361 (mouse 363) amino acids. The predicted size of the core protein is 37–38 kDa. Post-translational modification doubles the molecular size of human and mouse primary protein, bringing it to 80–95 kDa. The mature CD44s is a single-chain molecule composed of a distal extracellular domain, a membrane-proximal region (together containing 248 amino acids in humans and 250 amino acids in the mouse),

a transmembrane-spanning domain (23 amino acids), and a short (3 amino acids) or longer (70 amino acids), and much more abundant, cytoplasmic tail. The N-terminal domain contains six cysteine residues, which are possibly used to form one or more globular domains. This region, which includes the ligand (HA) binding sites of the molecule, displays ~30% homology with cartilage link protein and proteoglycan core protein, which also both bind HA. The N-terminus, transmembrane domain and cytoplasmic tail, but not the membrane-proximal region, exhibit high (~80–90%) interspecies homology. The cytoplasmic tail contains several optional phosphorylation sites (Figure 1a).

Differential utilization of the variable region exons yields at least 20 different CD44 isoforms; those expressing alternatively spliced exons are designated CD44v (v stands for variant) (Figure 1c). The CD44s and CD44v repertoire is further enriched by N- and O-glycosylation and glycosaminoglycanation (by heparan sulfate and chondroitin sulfate). The multistructural nature of CD44 (its molecular weight ranging from 85 to 230 kDa) may extend the ligand inventory of this molecule and further increase its optional functions.

Distribution

Standard CD44 (Figure 1) is a ubiquitous molecule expressed on many types of cells of lymphohematopoietic origin, including erythrocytes, T and B lymphocytes, natural killer cells, macrophages, Kupffer cells, dendritic cells and granulocytes. However, CD44s is also expressed on other cells, such as fibroblasts and cells of the central nervous system. After immunologic activation, T lymphocytes and other leukocytes transiently upregulate CD44v, particularly those containing V6 exon products. A CD44 variant, expressing exons V8 to V10 (CD44V8–10, also known as epithelial CD44 or CD44E), is preferentially expressed on epithelial cells. The longest CD44 isoform, CD44V3–10, was detected in keratinocytes (Figure 1c).

Function

Hyaluronic acid, the principal extracellular matrix (ECM) ligand of CD44, is a ubiquitous polysaccharide (glycosaminoglycan) with a high molecular mass

Figure 1 The CD44 glycoprotein, its exon map and examples of six alternatively spliced transcripts. (A) *Protein structure*. Using disulfide bonds, the amino terminus of the molecule forms a globular domain, or three globular subdomains. The circle and the 'downstream' ellipse represent areas that influence hyaluronate binding. The black track inside the circle refers to a region displaying ~30% homology with cartilage link protein and proteoglycan core protein, both showing HA-binding ability. The black track at the amino terminus (inside and outside the circle), transmembrane-spanning domain and cytoplasmic tail represent regions with ~80–90% interspecies homology. The alternatively spliced short cytoplasmic domain is nonproportionately represented by a small bar. The hatched track in the center indicates the nonconserved membrane-proximal region with ~35–45% interspecies homology. The variable region, containing various combinations of alternatively spliced exon products (see Part C), is inserted between amino acids 201 and 202 (mature protein) and marked by a zigzag track. ●, Potential *N*-linked glycosylation sites (only those of standard CD44 are shown); X, areas rich in serine/threonine, possible sites for *O*-linked glycosylation (those of the variable region are depicted arbitrarily); ◆, potential sites for glycosaminoglycans (chondroitin sulfate or heparan sulfate) incorporation; ⊕, potential sites for phosphorylation (only part of the sites are described). The symbols on the standard part of the molecule mostly refer to mouse CD44, whereas those of the variable region are based on information taken from both mouse and humans. (B) *Exon map*. The filled circles represent the exons of the constant regions. Empty circles represent exons that can be inserted by alternative splicing, resulting in the generation of the variable region. Note that exon V1 is not expressed in the human CD44. LP, leader peptide-encoding exon; TM, transmembrane-encoding exon; CT, cytoplasmic tail-encoding exons. (C) *Examples of alternatively spliced transcripts*. 1 and 2, standard CD44 with short and long cytoplasmic tails, respectively, which lack the entire variable region. 3, pMeta-1 (CD44V4–7). Exons V4, V5, V6 and V7 are inserted in tandem between exons 5 and 17. 4, pMeta-2 (CD44V6,7). Exons V6 and V7 are inserted between exons 5 and 17. pMeta-1 and pMeta-2 are known as 'metastatic' CD44, as their cDNA confers, upon transfection, metastatic potential on nonmetastatic rat tumor cells. Note that exon 16 is not expressed in both pMeta-1 and pMeta-2. 5, epithelial CD44 (CD44V8–10), expressed preferentially on epithelial cells. Exons V8, V9 and V10 are inserted between exons 5 and 16. 6, keratinocyte CD44 (CD44V3–10), one of the largest CD44 molecules known. Exons V3 through V10 are inserted between exons 5 and 16. (Reproduced from Naor *et al* (1997). © Academic Press.)

(10^6 – 10^7 Da), consisting of a linear polymer of the disaccharide (D-glucuronic acid [1-β-3] *N*-acetyl-D-glucosamine [1-β-4])_n. However, CD44 (or its chondroitin-sulfated version) also interacts with other

ligands of the ECM, such as collagen, fibronectin and laminin. Mucosal addressin, serglycin, osteopontin and class II invariant chain (Ii) are additional, ECM-unrelated, ligands of CD44. In many, but not in all,

cases CD44 does not bind HA unless it is stimulated by phorbol esters, activated by agonistic CD44-specific monoclonal antibody (mAb) or deglycosylated (e.g. by tunicamycin). Apparently, cytoskeleton-dependent receptor aggregation is required for HA binding, although cytoskeletal involvement can be bypassed by external cross-linking of cell surface CD44 molecules (e.g. with agonistic CD44-specific mAb or immobilized HA).

CD44 is a multifunctional receptor involved in cell-cell and cell-ECM interactions, cell traffic on endothelium or ECM, lymph node homing via binding to high endothelial venules, presentation of chemokines or growth factors to migrating cells, and transmission of growth signals, either independently or in association with other cell surface molecules. CD44 also participates in the uptake and intracellular degradation of HA, as well as in the transmission of signals mediating lymphohematopoiesis and prevention of apoptosis. Marked accumulation of CD44 (both standard and variant), and in some cases also of HA, is detected in areas of intensive cell migration and proliferation, as in wound healing, tissue remodeling, morphogenesis, inflammation and carcinogenesis.

Pathological aspects

Many cancer cell types, as well as their metastases, express high levels of CD44. Whereas some tumors, such as gliomas, exclusively display CD44s, other neoplasms, including brain metastases, gastrointestinal cancer, pancreatic adenocarcinoma, bladder cancer, uterine cervical cancer, breast cancer and non-Hodgkin's lymphomas, additionally and sometimes preferentially express CD44 variants. Hence, CD44, particularly its variants, may be used as diagnostic or prognostic markers of at least some human malignant diseases. Furthermore, it has been demonstrated in animal models that upon transfection with CD44s, or CD44v cDNA, nonmetastatic tumor cells acquire metastatic potential. In addition, injection of reagents interfering with CD44-ligand interaction (e.g. CD44s- or CD44v-specific mAb) inhibit local tumor growth and metastatic spread in murine species. In this context, CD44 may confer a growth advantage on some neoplastic cells, and consequently could be used as a target for cancer therapy. The functional significance of CD44 in malignant, autoimmune and infectious diseases, as well as in allergy, transplant rejection and graft-versus-host reaction, is yet to be established.

CD45

John Seavitt and Matthew L Thomas, Howard Hughes Medical Institute, Center for Immunology and Department of Pathology, Washington University School of Medicine, St Louis, Missouri, USA

CD45 is an abundant transmembrane protein-tyrosine phosphatase (PTPase) expressed uniquely by all nucleated cells of hematopoietic origin. With regard to lymphocytes, CD45 functions to activate Src-family members involved in antigen receptor signaling. Recent studies have demonstrated that several transmembrane PTPases, including CD45, are involved in regulating adhesion and this may be a common theme to their function.

Structure

CD45 contains a large extracellular domain, a single transmembrane region, and two cytoplasmic PTPase domains (Figure 1). cDNAs have been isolated from human, rat, mouse, chicken and shark and comparison of the predicted protein sequences indicates a conservation of domain structure. The extracellular domain of CD45 consists of three distinguishable regions: an O-linked carbohydrate domain, a cysteine-containing domain and a domain containing three fibronectin type III repeats (which also contain several cysteines). Electron microscopy analysis of the extracellular domain demonstrates that the O-linked carbohydrate region which is most membrane distal has an extended rod conformation. Multiple isoforms of CD45 exist, ranging in molecular weight from 180 to 220 kDa. The basis for the different isoforms is alternative splicing of exons that encode part of the O-linked carbohydrate region. Since this region has an extended conformation, the length of the extracellular domain is dramatically altered (28 nm for the low molecular weight isoform and 51 nm for the high molecular weight isoform) (Figure 2). The O-linked carbohydrate region is encoded by exons 3–8. cDNA cloning shows that exons 4, 5 and 6 (also named A, B and C) are spliced in a variety of combinations to give rise to eight distinct protein products. In addition, a ninth isoform is predicted to exist that is the product of a splice between exons 3 and 8. The proposed nomenclature for the different CD45 isoforms is shown in Table 1.

The extracellular domain contains numerous sites for N-linked carbohydrate addition. Indeed, CD45 is 25% carbohydrate by weight. Owing to the high level of expression on lymphocytes, 100 000 molecules per cell, and its large size, CD45 occupies approximately 10% of the lymphocyte cell surface and bears much of the carbohydrate of these cells. Further diversification of CD45 species is generated with the addition of carbohydrate groups by cell type-specific and developmentally regulated glycosyltransferases. The existence of specific modifications on CD45 has been demonstrated using monoclonal antibodies that recognize distinct carbohydrate groups.

The cytoplasmic domain of CD45 contains two tandemly arranged tyrosine phosphatase domains. Mutational analysis suggests the first, membrane proximal, domain is both necessary and sufficient for biological responses and contains most if not all the catalytic activity. This is consistent with the observation that the sequence of the second domain contains changes at critical amino acids in the active site signature motif 'HCSAGXGRTG'. Nonetheless, it is possible that the second domain does possess intrinsic phosphatase activity. Alternatively, the second domain may function to regulate substrate availability.

Expression patterns of CD45 isoforms

CD45 isoform expression is dynamically controlled in both leukocyte differentiation and cellular activation. Isoform expression by a given population has been characterized by both amplification of this region of the mRNA by reverse transcription-polymerase chain reaction analysis and by a large assortment of monoclonal antibodies that recognize epitopes affected by the use of the alternative exons. The antibodies that recognize epitopes encoded by the alternatively spliced exons 4, 5 and 6 have been termed CD45RA, B and C, respectively. For humans, an antibody termed CD45RO exists that recognizes

Figure 1 Human CD45. The variable exons 4, 5 and 6 are indicated. N represents site of potential N-linked glycosylation. C represents the location of cysteine residues in the extracellular domain.

the junction between exon 3 and 7; this is specific for the CD45 θ isoform. A similar reagent does not exist for mouse or rat CD45. Unlike CD45R0, however, the remaining CD45R antibodies are all capable of recognizing multiple isoforms (Table 1). This

Figure 2 Representation of the sizes of different CD45 isoforms compared to the T cell receptor (TCR). Estimates are based on either electromicroscopy data or inferred from crystal structures.

complicates the characterization of isoform expression with these reagents. In addition, many of the CD45R antibodies are sensitive to carbohydrate modifications and some are specific for carbohydrate epitopes, not all of which are dependent on the presence of the alternatively spliced exons. While the CD45R antibodies provide only a limited insight into the specific patterns of isoform expression, they have proved a powerful tool in demonstrating that CD45 isoform expression is exquisitely regulated by different leukocyte populations.

T cell lineages express distinct CD45 isoforms depending on compartment and activation state. Most thymocytes express the CD45 θ isoform, however there is increased expression of the higher molecular weight isoforms during thymocyte development. Of interest, very early thymocyte precursors that do not express TCR, CD4 or CD8 also stain for CD45R isoforms. This may indicate that thymocyte maturation is accompanied by cyclical expression of

Table 1 CD45 isoforms

Isoform	CD45R antibody recognition	Alternative exon usage						
CD45 α	A, B, C	3	4	5	6	7	8	
CD45 β	A, B	3	4	5		7	8	
CD45 γ	A, C	3	4		6	7	8	
CD45 δ	B, C	3		5	6	7	8	
CD45 ϵ	A	3	4			7	8	
CD45 ζ	B	3		5		7	8	
CD45 η	C	3			6	7	8	
CD45 θ	O	3				7	8	
CD45 τ		3					8	

CD45 splice isoforms depending on maturation stage.

Naive mature T cells express CD45R epitopes, and activation shifts isoform usage towards the CD450 form. Furthermore, functionally distinct T cell subsets have characteristic patterns of CD45 isoforms. CD8⁺ cytolytic T cells express higher levels of CD45RA, and distinct CD45R staining patterns on T helper subsets are observed. Carbohydrate specific monoclonals also reveal distinct compartmental and activation state epitopes on T cell CD45. Therefore, T cell CD45 isoform usage is dynamic and likely reflects a complex regulatory program.

B cells normally express the high molecular weight CD45 α isoform (also termed B220). However, cytokine treatment and viral transformation induce a change in staining pattern of the CD45R antibodies, including an increase in the expression of lower molecular weight isoforms. B cells also express carbohydrate epitopes on CD45 distinct from other cell lineages.

Monocytes express primarily the CD450 isoform. Similar to the effects in T and B lineages, activation events induce the appearance of CD45RA epitopes, suggesting the expression of higher molecular weight isoforms.

Thus, the polypeptide and carbohydrate composition of the CD45 extracellular domain is highly regulated in a cell type-specific, developmentally regulated and activation state-dependent manner.

CD45 ligands

As yet it is not clear how the extracellular domain regulates the defined biology of CD45. While a number of candidate ligands have emerged, it has been difficult to identify specific interactions that modulate the biological function of CD45. Due to its extensive modification with carbohydrate, it is likely that lectins will be important CD45 ligands.

CD22 is a cell surface cation-independent lectin with a specificity for α 2,6-linked sialic acid moieties and is expressed specifically on mature naive B cells. It is a member of the immunoglobulin (Ig) superfamily, with two alternatively spliced isoforms that contain five or seven Ig domains, respectively. Upon activation, CD22 is tyrosine phosphorylated and associates with the protein-tyrosine kinase p72^{syk} and the protein-tyrosine phosphatase SHP-1. Initially studied as a cell-cell adhesion molecule, recombinant CD22 interacts with a number of T cell surface proteins, among them CD45. However, the interaction is dependent upon the expression of α 2,6-sialyltransferase, which is only expressed by some leukocytes. CD45 cross-linking with CD22 augments early

T cell activation events. Nonetheless, it is unclear whether in an immune response CD22 and CD45 represent a cognate pair in which binding results in a change in signal transduction through either protein.

Galectin 1 is a widely expressed β -galactoside binding protein family member. It is a dimer of 14 kDa subunits, each with a separate carbohydrate binding site. A number of primary T cell populations and T leukemic cell lines undergo apoptosis upon treatment with galectin 1. This effect requires CD45 N-linked carbohydrates, although it may be negatively regulated by increased O-linked glycosylation on higher molecular weight isoforms of CD45. Interestingly, in the thymus, galectin 1 expression occurs in areas where apoptosis is thought to occur. The very high level of CD45 protein expression in the thymus makes it difficult to conclude that interaction of CD45 with galectin 1 results in thymic apoptosis, although the development of galectin 1-deficient mice may clarify this issue.

Other carbohydrate-binding proteins may serve as CD45 ligands. Serum mannan-binding protein (S-MBP) is reported to interact specifically with the CD450 isoform. S-MBP is a cation-dependent lectin that binds mannose and N-acetylglucosamine. Originally studied as a serum opsonin, S-MBP inhibits antigen receptor-induced T cell apoptosis. Although these results remain to be examined in greater detail, they suggest the extracellular domain of CD45 will have a role in regulating its biological function.

CD45 function

Genetic analysis using CD45-deficient cell lines and mice has been instrumental in delineating CD45 functions. CD45 is an important regulator of T and B lymphocyte antigen receptors and natural killer cell activation. With regard to T cells, CD45 functions to dephosphorylate and activate *src*-family member protein tyrosine kinases p56^{lck} and p59^{fyn}, a necessary first step for signaling through the T cell antigen receptor.

CD45 is expressed by leukocytes that do not express antigen receptors. Although analysis is not complete, this may be explained by a role for CD45 in cell-cell adhesion events and coordinate regulation of the cytoskeleton. Monoclonal antibodies to CD45 induce or inhibit aggregation of primary and transformed lymphocyte cell lines. This latter inhibition is also correlated with reduced levels of tyrosine phosphorylation on ICAM-3 and LFA-1. Immobilized CD45-specific monoclonal antibodies promote the adherence to plastic of T cell lines in conjunction with an increase of cellular phosphotyrosine. Cell adhesion events involve the cytoskeleton, and CD45

interacts with the cytoskeletal component fodrin (non-erythroid spectrin). Association with the cytoskeleton via fodrin or other molecules may control the ability of CD45 to interact with its substrates. Whether there are distinct mechanisms by which CD45 regulates antigen receptor signaling and adhesion is not clear. However, it is of interest to note that in lymphocytes CD45 associates with the lymphocyte-specific protein termed CD45-associated protein (CD45AP). CD45AP contains a short extracellular domain, a single transmembrane region, and a 146 amino acid cytoplasmic domain that contains a putative WW domain (a protein-binding module containing two conserved tryptophans [W]) and an acidic domain. CD45 associates with CD45AP through the transmembrane domain, and thus the WW domain and the acidic domain may associate with other proteins. The possibility exists that CD45AP may affect the substrates that CD45 interacts with and, as such, may regulate the ability of CD45 to function in antigen receptor signaling and/or adhesion.

The ability of the CD45 extracellular domain to regulate function has been pursued either by expressing in CD45-deficient cells chimeric proteins containing a different extracellular domain or by expressing distinct CD45 isoforms. Reconstitution of CD45-deficient cells, in which the extracellular domain has been deleted or exchanged, partially reconstitutes antigen receptor signaling. Interestingly, while expression of a chimeric protein with the epidermal growth factor (EGF) receptor extracellular and transmembrane domains and the CD45 cytoplasmic domain does reconstitute some antigen receptor signals, the addition of EGF ablates the response immediately, presumably as a result of receptor dimerization. This is consistent with the inhibitory effects on T cell activation seen with some monoclonal antibodies against CD45. However, it is not known whether these experimental systems mimic a physiologically relevant mode of CD45 regulation.

Expression of distinct CD45 isoforms in either transgenic mice or CD45-deficient cell lines suggests that the extracellular domain is important in regulating function. Specific expression of CD45 α but not CD45 β in transgenic animals results in an augmented proliferative response. Furthermore, it has been suggested that the lower molecular weight CD45 β isoform more readily associates with the TCR complex to increase signaling capacity. Therefore, the extracellular domain appears to have the capacity to regulate CD45 function, although the

mechanism is unknown. Characterization of CD45 ligands and their ability to modulate CD45 function will help clarify this issue.

CD46 (MEMBRANE COFACTOR PROTEIN, MCP)

M Kathryn Liszewski and John P Atkinson, Department of Internal Medicine, Washington University School of Medicine, St Louis, Missouri, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The complement system consists of a group of sequentially interacting proteins that promote the inflammatory response and facilitate the destruction of microorganisms. The system must be tightly regulated to prevent activation in the fluid phase (i.e. no target) and on host tissue (i.e. inappropriate target). Nearly half of the complement proteins serve in regulation. One such inhibitory protein is CD46, membrane cofactor protein (MCP). This regulator is a type one transmembrane protein that serves as a cofactor for the factor I-mediated proteolytic cleavage and inactivation of C3b and C4b deposited on self tissue. CD46 performs this role intrinsically in that it protects the cell on which it is expressed, not neighboring cells. CD46 is also the measles virus receptor and is involved in the adherence of *Streptococcus pyogenes* (group A streptococcus) to epithelial cells. CD46 belongs to a group of structurally, functionally and genetically related proteins called the regulators of complement activation (RCA) that includes decay-accelerating factor (DAF; CD55), complement receptors 1 (CR1; CD35) and 2 (CR2; CD21), and the plasma proteins factor H and C4-binding protein.

Structural characteristics

CD46 possesses an unusual electrophoretic pattern in that it consists of two rather heterogeneous protein species of 51–58 kDa ('lower' band) and 59–68 kDa ('upper' band). This variability is inherited as three phenotypic patterns consisting of upper band predominance in 65% of the population, equivalence of both bands in 29% and predominance of the lower band in 6%. This heterogeneity represents a size polymorphism and relates to CD46 being expressed as a family of at least four isoforms that arise by alternative splicing of a single gene (Figure 1). A dominating characteristic of CD46 is the presence of four of the repeating motifs called complement control protein repeats (CCPRs) (also called short consensus repeats). These are the building blocks of RCA proteins that contain the binding sites for C3b and C4b. Sites for N-linked glycosylation are found in CCPR-1, -2 and -4. Following the CCPRs is an area enriched in serines, threonines and prolines (STP) that is extensively O-glycosylated.

This domain consists of 14 or 29 amino acids depending on whether the STP exon B (15 amino acids) is spliced out. The presence of STP-B produces the higher molecular weight protein isoforms (possessing more sialic acid) while its absence generates the lower molecular weight forms. Following this is a tract of 12 amino acids of unknown significance, a transmembrane region, intracytoplasmic anchor and one of two alternatively spliced cytoplasmic tails (CYT-1 of 16 amino acids or CYT-2 of 23 amino acids). The CD46 gene consists of 14 exons and 13 introns with a minimum length of 43 kb and resides in the RCA cluster on the long arm of chromosome one (1q3.2). A partial duplicate of CD46 is also present in this cluster but no mRNA for this species has been identified.

Functional role

Host cells must be protected from inadvertent complement activation at sites of inflammation and from the continuous, natural 'tickover' of C3. A biochemical mechanism to regulate C3b/C4b is termed 'cofactor' activity. In this process, CD46 interacts with C3b or C4b to promote their limited enzymatic cleavage by factor I, a plasma serine protease. CD46 possesses 'intrinsic' cofactor activity, i.e. it protects the cell on which it is anchored, not bystander cells.

The reason for the expression of four isoforms in a given cell or tissue is only partially understood. For example, the cytoplasmic tails of CD46 mediate the differential processing of CD46 precursors. Isoforms bearing tail 1 (CYT-1) processed into their mature forms four times faster than isoforms with tail 2 (CYT-2). Additionally, the BC isoforms provide enhanced cytoprotection against the classical pathway as compared to C isoforms. The presence of distinct consensus phosphorylation signals on the cytoplasmic tails suggests roles in cell signaling.

The CCPRs are the sites of functional activity for CD46 and other RCA proteins. C4b-binding and cofactor activity map to CCPRs 2, 3 and 4. To regulate C3b, the third and fourth CCPRs are necessary for binding while 2, 3 and 4 are needed for cofactor activity.

Figure 1 Genetics and structure of membrane cofactor protein (MCP; CD46). (A) the genomic organization of the alternatively spliced CD46 reveals 14 exons and 13 introns for a minimum length of 43 kb. 5'UT/SP, 5' untranslated region/signal peptide; CCPR, complement control protein repeat; STP^A, STP^B, STP^C are the segments enriched in serines, threonines and prolines; UK, region of unknown functional significance; HY¹ and HY² are hydrophobic regions 1 and 2; CYT¹, cytoplasmic tail 1; CYT²/3'UT, cytoplasmic tail 2 and 3' untranslated region. (B) The electrophoretic profile of the protein shows three phenotypic patterns: lower band predominant, equal banding, and upper band predominant. The apparent molecular weight of all species increases with reduction. (C) Structural model shows the four primary isoforms of CD46—note the alternatively spliced STP and cytoplasmic tail regions.

Tissue distribution

CD46 is widely expressed on host tissue, a logical consequence of the critical role it plays in self-protection. Although most cells express CD44, erythrocytes are an interesting exception. Soluble forms are present in low concentrations in plasma, tears, saliva and seminal fluid and are increased in plasma in the presence of certain malignancies.

As mentioned, CD46 is expressed as a family of isoforms. While most cells in a given individual express the same ratio of the four isoforms, a predominance of certain species has been noted in brain, salivary gland, kidney and fetal heart. Different molecular weights resulting from variable glycosylation have been noted on granulocytes and spermatozoa. Tissues including kidney, skin, reproductive, eye, thyroid, liver and synovium differ in the relative expression and distribution pattern of CD46. Additionally, malignant and transformed cells tend to express high amounts of CD46.

Homologous proteins of other species

CD46 has been identified in primates, pigs, guinea pigs and rabbits. A functional homolog has been characterized in the mouse (Crry/p65) and rat (5I2 antigen). However, these resemble the human complement receptor CR1 in that they possess both cofactor activity and decay-accelerating activity. However, human CR1 has limited tissue distribution.

CD46 in other biological areas

Since the identification of CD46 as a C3b-binding protein more than a decade ago, its biologic and pathophysiologic role has expanded. CD46 is the receptor for measles virus. Additionally, CD46 is involved in the adherence of *Streptococcus pyogenes* (group A streptococcus). Recently, it was found that human immunodeficiency virus 1 (HIV-1) can incorporate complement control proteins CD46, CD55

and CD59 as common surface constituents in order to promote resistance against complement.

CD46 also is of interest in transplant biology. Acute rejection of the organs of other species is in part mediated by the complement system. To overcome this, complement regulators are being engineered to produce transgenic pigs whose organs will be used in xenotransplantation.

In reproductive biology, CD46 is abundantly expressed at the maternal–fetal interface, on fetal tissue and on the inner acrosomal membrane of spermatozoa. Alterations in function or expression of CD46 may play a role in habitual abortion or infertility. The surprising acrosomal site for CD46 expression may be part of the egg–sperm attachment mechanism and/or protect against C3b deposition during penetration by spermatozoa.

CD59

Alexandra Davies and **Peter Lachmann**, Department of Medicine, University of Cambridge, Medical Research Council Centre, Cambridge, UK

CD59 is an 18 kDa membrane glycoprotein whose primary function is to regulate the activity of the complement membrane attack complex (MAC). Alternative names for CD59 include protectin, membrane inhibitor of reactive lysis (MIRL), homologous restriction factor 20 (HRF20) and membrane attack complex inhibitory factor (MACIF). CD59 is attached to the outer layer of the membrane by a glycosylphosphatidylinositol (GPI) anchor and is very widely distributed (Table 1). It has also been detected in a number of body fluids, but often in association with lipoproteins or small membrane vesicles, and has probably been shed from cell surfaces

with its anchor intact or released enzymatically (Table 1). There is no evidence for a secreted form of the protein. The molecule is now extremely well-characterized and species homologs are known in a variety of primates as well as the rat, sheep, pig and mouse. Functionally analogous proteins have also been described in some microorganisms.

CD59 inhibits the formation of the MAC by binding to sites on C8 and C9, thus blocking the uptake and incorporation of multiple C9 molecules into the complex. CD59 from any given species interacts with C8 and C9 from heterologous species with variable efficiency, working best with homologous proteins.

Table 1 Cells and tissues expressing CD59

<i>Liver</i>	<i>Pancreas</i>
Bile canaliculi	Ductal epithelium
Bile duct	<i>Peripheral nervous system</i>
<i>Lung</i>	Schwann cells
Bronchi and bronchioles	Endothelial cells
<i>Kidney</i>	Neurons
Glomerular capillaries	<i>Eye</i>
Glomerular epithelial cells	Lacrimal gland
Distal tubules	Acinar cells
Collecting ducts	Retinal pigment epithelium
<i>Central nervous system</i>	Cornea and conjunctiva
Myelin	<i>Body fluids</i>
Microglia	Serum (low levels)
Neurons	Urine
Oligodendrocytes	Milk
Astrocytes	Seminal plasma
<i>Neoplastic cells</i>	Cerebrospinal fluid
Melanoma	Saliva
Malignant glioma	<i>Other</i>
Colonic adenocarcinoma	Hematopoietic cells
Thyroid carcinomas	Vascular endothelium
<i>Reproductive system</i>	Prostatic epithelium
Unfertilized oocytes	Nasal epithelium
Preimplantation embryos	Chondrocytes
Amniotic epithelium	Salivary duct
Syncytiotrophoblast	Thyroid follicular cells

This forms the basis for the phenomenon of 'homologous restriction' of lysis, a term used to describe the relative inefficiency with which complement lyses homologous cells. The physiological importance of the complement inhibitory role of CD59 is demonstrated in the acquired hemolytic disease paroxysmal nocturnal hemoglobinuria (PNH; see below), in which affected cells are deficient in CD59 and other complement regulatory proteins and are extremely sensitive to lysis. Roles for CD59 in T cell adhesion and activation have also been proposed but not firmly established.

Protein and gene structure

cDNAs for CD59 have been isolated by several independent groups. The nucleotide sequence encodes a precursor polypeptide of 128 amino acids in length, the first 25 residues constituting a signal peptide. The sequence contains one site for N-linked glycosylation at Asn18, and the carbohydrate attached here is a common biantennary structure accounting for approximately 25% of the molecular weight of CD59. At the C-terminus there is a hydrophobic stretch of residues characteristic of proteins which are processed to carry a GPI anchor. The presence of such an anchor in the case of CD59 was originally

confirmed by release of the protein from various cell surfaces by phosphatidylinositol-specific phospholipase C. Subsequently, protein sequencing of tryptic fragments and nuclear magnetic resonance (NMR) studies of the protein purified from human urine have indicated that the GPI anchor is attached to Asn77. The protein contains a total of 10 cysteine residues which form disulfide bonds as follows: Cys3-26, Cys6-13, Cys19-39, Cys45-63, Cys64-69.

CD59 is unique in the complement control protein superfamily in that it bears no structural or immunologic relationship with other member proteins, although these are distinctly related to one another and encoded by genes which are situated together in the RCA (regulators of complement activation) region on chromosome 1. The gene for CD59 is in contrast located on the short arm of chromosome 11, distributed throughout over 27 kb of genomic DNA. Although initial studies identified four exons, a fifth alternately spliced exon has recently been discovered between what were originally considered to be exons 1 and 2. The transcriptional start site for both forms of mRNA is the same. Since the newly identified exon occurs within the 5' untranslated region of the CD59 transcript there is still no evidence as yet to suggest that there are alternative forms of the mature protein. Both types of transcript are expressed concordantly in all the cell types analyzed so far, and their expression appears to be regulated similarly. The purpose of the alternately spliced exon is therefore not known.

The structure of the CD59 gene is similar to that of the murine Ly-6 antigens and of the human urokinase plasminogen activator receptor (HUPAR). These and other proteins such as the mouse thymocyte and B cell antigen ThB, and the squid glycoprotein SGP2, constitute a separate family of proteins which share some sequence homology (in particular, conserved cysteine residues) and therefore some structural similarity. CD59 has on occasion been proposed as the human homolog of the murine Ly-6 antigens, despite only 25% sequence identity between the two, and differences in the pattern and regulation of gene expression. However, the recent cloning of mouse CD59 clearly demonstrates that CD59 and Ly-6 are distinct proteins.

Inhibition of complement lysis

Mechanism of action

CD59 is the major cell surface inhibitor of the complement membrane attack complex (MAC), a multi-molecular assembly of complement components C5 to C9 which forms as a consequence of complement activation. At the C5b-7 stage of assembly, a labile

binding site is exposed on C7 which allows the growing MAC to bind cell membranes; then as C8 and multiple copies of C9 are incorporated, the complex inserts further into the membrane and finally forms a functional pore through the bilayer, leading to cell lysis. CD59 prevents lysis by interfering with the assembly of a fully functional MAC, binding to C8 in the C5b-8 complex and thereby blocking the uptake and polymerization of C9 (Figure 1). Binding sites for CD59 are located on the α subunit of C8 and on the C9b fragment (the putative membrane-binding domain) of C9. However, the regions on CD59 which are involved in this interaction have not yet been fully elucidated. Studies using proteolytic fragments of the protein implicate sites in the N-terminal region. Some early observations that deglycosylated CD59 did not inhibit cell lysis suggested that the carbohydrate moiety was also important for function, although paradoxically the deglycosylated CD59 retained its ability to bind to isolated C8 and C9 immobilized on plastic. One possible explanation for this is that the presence of the carbohydrate moiety somehow influenced the orientation of CD59 on the cell surface and thereby influenced its interaction with the MAC, without being directly involved in the binding of C8 and C9. Subsequent studies in which the site of N-linked glycosylation was removed from the CD59 cDNA by site-directed mutagenesis have demonstrated that the carbohydrate is not necessary for complement inhibitory activity.

CD59 deficiency and paroxysmal nocturnal hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired hemolytic disease characterized by bouts of intravascular hemolysis. The disease is caused by somatic mutation in a pluripotent stem cell of the hematopoietic system, leading to the appearance in the circulation of a clone of cells exhibiting increased sensitivity to complement lysis. Depending upon the point in the lineage at which mutation occurs, erythrocytes, granulocytes, monocytes, platelets and lymphocytes may all be affected. Cells in the affected clone are abnormally sensitive to complement because they fail to express GPI-anchored proteins on their surfaces and therefore lack CD59 and decay accelerating factor (DAF), another complement regulatory protein. The defect in PNH arises from mutation of the PIG-A gene whose product is an enzyme involved in the biosynthesis of the GPI anchor. Various mutations in PIG-A have been identified, and since PIG-A is carried on the X chromosome, loss of function in the single active allele is sufficient for disease to be manifest. There is an isolated case of CD59 deficiency due to a mutation in

Figure 1 Model for the mechanism of action of CD59. Two putative binding sites on C5b-8 for C9 are shown. C9 binds loosely in its globular form at site 1 and at this stage may be displaced by other C9 molecules; this may be demonstrated experimentally by holding the temperature at 4°C (A). However, at 37°C C9 normally unfolds and interacts with site 2 on the C5b-8 complex (B), begins to penetrate the cell membrane, and exposes sites for interaction with additional C9 molecules which polymerise to form a transmembrane pore (C). In the presence of CD59, the initial interaction of C9 with C5b-8 occurs, but the binding of CD59 to C8 prevents the C5b-8 catalyzed unfolding and insertion of multiple C9 molecules into the membrane, and thereby blocks cell lysis. (Reproduced with permission of Blackwell Science Ltd, from Meri S, Morgan BP, Davies A *et al* (1990) Human protection (CD59), an 18,000–20,000 MW complement lysis restricting factor, inhibits C5b-8 catalyzed insertion of C9 into lipid layers. *Immunology* 71: 1–9).

the CD59 gene. Despite having all the other GPI-anchored proteins, including DAF, the patient with CD59 deficiency suffers from a PNH-like condition characterized by hemolysis. This underlines the importance of CD59 as the major factor for regulation of complement lysis on erythrocytes.

Role in T cell activation

Antibody cross-linking of CD59 on the surface of human T cells induces a rise in intracellular calcium, inositol phosphate production, release of cytokines and cell proliferation. These phenomena occur when any GPI-anchored proteins are cross-linked in the membrane, and the mechanisms by which their assembly in the *outer* layer of the membrane can transmit signals to the *interior* of the cell are currently under investigation. Whether or not the observed effects of experimentally cross-linking CD59 using antibody have any real significance depends upon there being a physiological ligand for CD59. There have been several claims that like CD58 (LFA-3) and CD48, CD59 is a ligand for CD2, a molecule involved in T cell activation, but an equal number of reports dispute this. As yet the role of CD59 in the processes of T cell activation remains equivocal.

Microbial counterparts of CD59

It has been to the advantage of many microbial pathogens to acquire mechanisms for immune evasion. For example, an open reading frame encoding a sequence highly homologous to that of human and various monkey species of CD59 has been identified in the genome of herpesvirus saimiri (HVS), whose natural host is the squirrel monkey. It appears highly likely that the virus has captured this sequence from its host during the course of evolution. Preliminary studies indicate that the sequence does indeed encode a functional protein, so expression of this sequence by HVS could be considered as a virulence factor in aiding the virus to evade the detrimental effects of complement activation. Complement-inhibiting proteins that appear to have some antigenic relationship to CD59 have also been described in *Entamoeba histolytica* and *Schistosoma mansoni*. The *E. histolytica* protein is an integrin-like molecule consisting of two subunits, one of which shares very limited sequence homology with CD59. A cDNA for the *S. mansoni* protein has not yet been isolated. Since many pathogens are adept at avoiding destruction by the complement system, it is highly likely that other

microbial proteins will emerge that are functionally, if not structurally, related to CD59 or the other human complement control proteins.

CD59 transgenics and xenotransplantation

The shortage of suitable donor organs for transplant surgery has led to the proposal that animal organs be used instead. A major problem with this is that of hyperacute rejection, whereby discordant xenografts come under attack within minutes, and are destroyed by complement that has been activated by naturally occurring antibodies in the host that recognize carbohydrate epitopes in the xenograft. A major strategy now being researched to overcome this is the production of transgenic animals (mainly pigs) that carry the genes for human complement control proteins, including CD59. These human proteins are expressed in a wide range of tissues in the transgenic animals, sometimes at very high levels, and have been shown to confer increased protection upon endothelial and other cell types against human complement. Although these results seem very promising, a major drawback to the use of xenotransplantation is the possibility that xenografts may harbor viruses or other microbes that could be extremely harmful to a human host, and this is currently the main objection to proceeding with clinical trials.

CELL-MEDIATED IMMUNITY

Frank W Fitch, The Ben May Institute, Division of Biological Sciences,

Cell-mediated immunity is mediated by T lymphocytes; humoral immunity, by antibodies. These distinctions are based on observations that delayed-type hypersensitivity (DTH) and other manifestations of cell-mediated immunity can be adoptively transferred by lymphoid cells but not by serum from sensitized animals, while other manifestations of immunity can be passively transferred by serum from immune animals. Cell-mediated and humoral immunity can exist in isolation: some chemicals induce contact sensitivity, a manifestation of cell-mediated immunity, but do not induce production of antibodies, and some antigens can stimulate antibody production in the apparent absence of T lymphocytes. However, cell-mediated and humoral immunity usually develop concurrently *in vivo*, and the two responses often act synergistically. For example, although DTH can be adoptively transferred with T lymphocytes, the intensity of the reaction is usually greater if antibody is also passively administered. There also are conceptual difficulties inherent in these definitions: antibodies are produced by cells, and cells participate in many of the protective reactions mediated by antibodies. Also, T lymphocytes carry out many of their functions through soluble products which they secrete following stimulation with antigen.

In the early 1880s, Elie Metchnikoff proposed that inflammation had a protective role in responses to pathogens, and that phagocytic cells, rather than being harmful, constituted the primary line of defense through their ability to ingest and digest invading organisms. However, the contrary view, that humoral antibody played the dominant role, was furthered by the demonstration of bactericidal properties of immune serum and the protective effects of antibodies against bacterial exotoxins. Although in the early 1900s the phenomenon of DTH was shown to be unrelated to circulating antibody, it proved difficult to determine with certainty the relative contributions of humoral and cell-mediated immunity until the central involvement of lymphocytes in immune responses was established finally in the late 1950s. In the early 1960s, several serendipitous observations led to the identification of two separate lymphocyte lineages, based on their development pathways: B lymphocytes, which originate in the bursa of Fabricius in birds and in the

bone marrow of mammals; and T lymphocytes, which develop within the thymus from precursors originating initially in the yolk sac and later in the bone marrow.

These two developmentally distinct sets of lymphocytes were soon shown to have different functions: B cells display and secrete antibody molecules which react with intact antigen molecules; T cells react with processed antigen fragments which are associated with molecules of the major histocompatibility complex (MHC). T lymphocytes carry out some functions, such as the lysis of target cells that express the appropriate antigens, through direct cell-to-cell contact, but they exert many of their effector functions through secreted hormone-like proteins, called cytokines, which modulate the activities of various cells, including lymphocytes and phagocytes.

Although the classical manifestations of cell-mediated immunity are phenomena which can be observed only *in vivo*, it is difficult to dissect the cellular and biochemical processes involved in these reactions in animals. Therefore, a variety of responses by antigen-stimulated T lymphocytes have been used as surrogate cell-mediated responses *in vitro*. It is generally assumed that these responses – which include T lymphocyte proliferation, cytolytic activity, ‘helper’ functions, and/or secretion of cytokines – relate to manifestations of cell-mediated immunity observed *in vivo*. However, none of the phenomena of cell-mediated immunity observed in sensitized animals have been characterized fully in cellular and biochemical terms.

Recognition of antigens by T lymphocytes

T and B lymphocytes recognize antigens in fundamentally different ways. Both T and B lymphocytes have extensive antigen-specific receptor repertoires and can react with a very large number of different antigens, each being able to distinguish among more than 10^7 distinct antigenic determinants. However, entirely different genes which are located on different chromosomes are used to construct their cell surface receptors for specific antigens. Nevertheless, they use similar mechanisms to produce their antigen receptors, employing a limited number of gene segments which are combined in many different ways to construct a very large number of conformationally

distinct polypeptides. The T cell receptor (TCR) for antigen consists of a heterodimeric structure, which in most T cells consists of α and β chains. However, a minority of peripheral T cells (approximately 5%) employ a TCR composed of structurally related but distinct γ and δ polypeptides. Such T cells are the dominant population in most surface epithelia in mice. There is generally allelic exclusion in the expression of genes encoding TCR peptides so that a given T lymphocyte expresses only one functional α and one β gene or one γ and one δ gene. The use of α and β or γ and δ chain polypeptides in various heterodimeric combinations contributes to the very large repertoire. Somatic mutation, which contributes to the affinity maturation of antibodies, does not appear to take place in T lymphocytes.

T lymphocytes react with antigen fragments associated with molecules of the MHC expressed by the individual in which the T lymphocytes arose. During the course of maturation in the thymus, T lymphocytes appear to be positively selected for the ability to recognize self antigens, but those T lymphocytes which react too strongly with self antigens appear to be negatively selected and deleted. The vast majority of cells which enter the thymus fail to survive these selection processes and die; probably less than 5% of thymocytes find their way to peripheral lymphoid tissues as mature T lymphocytes.

In addition to rearrangements of genes encoding the TCR and subsequent selection events, maturation of T lymphocytes in the thymus also involves sequential expression of a number of lineage-specific molecules, including CD4 and CD8 which distinguish different T lymphocyte subsets. The most immature cells in the thymus express neither of these cell surface structures and have not rearranged their TCR genes. The TCR is expressed first in cells which express both CD4 and CD8; CD4⁺ and CD8⁺ subsets of T lymphocytes develop from this 'double-positive' population. Expression of CD4 is associated conventionally with 'helper' cell functions and CD8 expression with cytolytic activity, but these distinctions are by no means absolute. Many CD4⁺ T cells have cytolytic capabilities, and at least some CD8⁺ T cells can carry out helper functions. The mutually exclusive expression of CD4 or CD8 correlates better with the class of MHC antigen which serves as the restriction element for antigen recognition than it does with function: CD4⁺ T cells usually recognize antigenic peptides associated with class II MHC molecules, while CD8⁺ T cells are usually restricted to recognition of peptides associated with class I MHC molecules. Both CD4 and CD8 have 'coreceptor' function, probably by bringing the protein tyrosine kinase *lck* into the TCR-antigen complex.

Full activation of CD4⁺ T cells requires two signals: one delivered through TCR, and a second 'costimulatory' signal which is not antigen specific. Stimulation of the TCR alone induces anergy, defined as the long-lived inability to secrete interleukin 2 (IL-2) and proliferate in response to antigenic stimulation. CD28 has been identified as the dominant costimulatory molecule expressed by T cells. While stimulation through CD28 alone has little effect, interaction of CD28 with B7 on antigen-presenting cells (APCs) in conjunction with TCR engagement augments significantly the secretion of multiple cytokines. A full understanding of the phenomenon of costimulation is complicated by the fact that these counterreceptor families have multiple members: CTLA-4, which is structurally similar to CD28, also binds to B7-1 and B7-2, which also are related structurally. These B7 family members are not expressed concordantly on all cell types, and their expression is differentially regulated. While most resting T cells express CD28, CTLA-4 is expressed only on activated T cells. An attractive model proposes that interactions between CD28 and B7-2 provide costimulation for T cell activation, while interactions between CTLA-4 and B7-1, both of which are expressed later in immune responses, terminate ongoing responses.

Several other cell surface molecules are involved in the interaction between T lymphocytes and APCs. CD2, expressed on all human thymocytes and peripheral T cells, interacts with LFA-3, a broadly distributed glycoprotein. The T lymphocyte integrin, LFA-1, interacts with ICAM-1, a heavily glycosylated and widely expressed molecule, and with ICAM-2. There are probably additional cell surface structures which are important in interactions of T lymphocytes with other cells. While these structures enhance cell-to-cell contact, many of them also appear to be involved in cell activation, either participating directly in signaling events or indirectly by modulating, either positively or negatively, signals induced through the TCR.

Manifestations of cell-mediated immunity *in vivo*

Allograft rejection, DTH, and graft-versus-host disease are manifestations of T cell-mediated immunity *in vivo*. In addition, much of the protective immunity to viral and some bacterial infections is also dependent upon cell-mediated immunity. A subset of murine CD4⁺ T cells designated T_H1 appears to mediate DTH, while the T_H2 subset does not. Since these subsets differ in the array of cytokines they secrete, it is likely that DTH is mediated by parti-

cular cytokines. The pathophysiological processes that lead to organ allograft rejection are not well characterized, but it is likely that cytokines play a major role here as well. Mechanisms of allograft rejection depend on the nature of the antigens being recognized as well as the type of graft involved. Antibodies also are produced in response to allografts, and antibody-mediated vascular lesions often are prominent. T lymphocytes presumably can injure allografts of dispersed cells (bone marrow or lymphoid cells) by direct effector mechanisms such as cytotoxicity. T cells can also act indirectly through secreted cytokines (lymphotoxin or tumor necrosis factor) which can themselves directly injure target cells or through effects of cytokines (interferon γ , IFN γ) on macrophages to increase their killing and other activities. Vascularized allografts (kidney, heart and liver) can be rejected through effects on blood vessels rather than through primary injury to the parenchymal cells in these organs. Other tissue grafts can be rejected by mechanisms which interfere with revascularization. Although it is clear that T lymphocytes mediate these reactions, details of the cellular and biochemical processes that are involved remain obscure.

Manifestations of cell-mediated immunity *in vitro*

A number of model systems have been studied *in vitro* to evaluate the molecular mechanisms controlling T cell responses; these include proliferation, induction of cytotoxic activity, expression of helper functions for antibody production, secretion of cytokines and biochemical signaling events. Clonal populations of T lymphocytes which retain normal phenotypic characteristics and monoclonal antibodies reactive with different T cell surface structures have greatly facilitated the detailed analysis of these correlates of cell-mediated immunity *in vitro*. Monoclonal antibodies, which react with the TCRs, can serve as surrogate antigens, making it possible to distinguish the effects initiated by stimulation of the TCR from those involving other cell surface structures.

Many of the biological effects of T cells are mediated by secreted cytokines which affect the activities of different kinds of target cells. Different arrays of cytokines are produced by different T cell subsets following stimulation, and regulatory mechanisms that control which cytokines a particular T cell will secrete are beginning to be defined. It is clear that the array of cytokines secreted is of major functional significance. More than 15 different cytokines have been identified and their genes cloned. Their properties have been defined unequivocally, using

products obtained by recombinant DNA technology. Most cytokines act on several different cell types.

Most if not all T lymphocyte proliferation is due to growth factors secreted by T cells. T lymphocytes stimulated with antigen are induced to express receptors for transferrin and for T cell growth factors, and they undergo cell division in response to cytokines having T cell growth factor activity. IL-2 was first identified on the basis of its ability to stimulate proliferation of T cells, and was thought initially to be the only T cell growth factor. Subsequently, however, IL-2 was found to stimulate proliferation of B cells as well. IL-4 is an additional T cell growth factor; it was first identified as a stimulatory factor for B cells. Both IL-2 and IL-4 serve as autocrine growth factors for the T cells which secrete them, and as paracrine growth factors for T cells which do not. IL-4 favors the development of cells that produce IL-4, IL-15, produced preferentially by nonlymphoid cells, also stimulates T cell growth. Uncontrolled growth of T cells that would occur through the autocrine pathway is prevented by regulatory processes which include desensitization of the T cell receptor for antigen, limitation of the period of time that cytokines are secreted, and modulation of the level of expression of growth factor receptors.

Much of the 'help' provided by T lymphocytes for antibody production is mediated by secreted cytokines. However, resting B cells require interactions with cell surface molecules expressed by T cells. The interaction of CD40, expressed constitutively by B cells, with CD40 ligand, expressed by T cells only upon activation, renders B cells responsive to IL-4 and other cytokines. This interaction stimulates the T cell as well. The most efficient help for B cells is provided by the T cell subset designated T_H2 , which secretes IL-4 and IL-5. These cytokines provide optimal B cell proliferation and differentiation. The T_H1 subset, which secretes IL-2 and IFN- γ but not IL-4 or IL-5, also may be able to provide help for B cells. Cytokines influence which antibody isotype is produced: IL-4 is required for immunoglobulin E (IgE) responses, and IFN- γ and perhaps other factors from T_H1 cells favor IgG2a production. In addition to their effects on antibody production by B cells, cytokines secreted by CD4⁺ helper T cells enhance generation of CD8⁺ cytotoxic T cells. Thus, both T_H1 and T_H2 cells appear to be able to serve as helper cells, although they may function in different situations and promote qualitatively different immune responses.

In addition to the antiviral effects that led to its designation, IFN- γ causes increased expression of both class I and class II MHC antigens by macrophages and activation of macrophages for greater

killing of ingested microorganisms. However, IFN- γ also inhibits the effects of IL-4 on B cells and inhibits proliferation of bone marrow cells induced by several other T cell cytokines. IL-6, which is secreted by some nonlymphoid cells, acts as a B cell stimulation and differentiation factor and stimulates the release of acute-phase reactants from liver cells; IL-3 stimulates pluripotential bone marrow stem cells and mast cells. IL-10 inhibits the ability of macrophages to stimulate T_H1 cells. IL-12 increases production of IFN- γ by naive T cells. Granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates granulocyte and monocyte precursors. Tumor necrosis factor α (TNF- α) is produced by macrophages as well as T cells; it causes leukocytosis, fever, weight loss and necrosis of some tumors. Lymphotoxin also kills target cells; its gene is closely linked to that for TNF- α , and there is 30% homology in the sequence of amino acids for these two proteins. Most major cytokines have probably been identified. These and other interactions among cytokines are important in the regulation of immune responses.

Although cytolytic activity has usually been associated with CD8⁺ T cells, many CD4⁺ T cells also have cytolytic potential. There are several distinct cytolytic mechanisms. Perforin, a complement-like molecule, is found in intracellular granules in cytolytic T cells and natural killer (NK) cells. Interaction between surface-bound Fas ligand, expressed by activated T cells, with Fas, expressed by some target cells, can also mediate cytotoxicity. Cytokines, such as lymphotoxin or TNF, can kill some target cells. The killing process is unidirectional, and the T cell is not injured by the cytolytic events. NK cells appear to use similar killing mechanisms as CD8⁺ cytolytic T cells. Most NK cells, at least in the human, appear not to be of the T cell lineage; the receptors that NK

cells use to interact with target cells have not been well characterized. Also, NK cells can mediate antibody-dependent cytotoxicity (ADCC); this involves interactions of Fc receptors on NK cells with antibody bound to target cells.

Conclusion

Different T cell subsets have different roles in the various features of cell-mediated immunity, although these roles have not been fully characterized. In several experimental infections, the patterns of disease indicate preferential involvement of one or another T cell subset. Factors which influence the development of the several T lymphocyte subsets are beginning to be understood, and the mechanisms that selectively regulate their responses have been partially defined.

CELL-MEDIATED LYSIS

David W Lancki, Frank W Fitch Monoclonal Antibody Facility, The Gwen Knapp Center, Chicago, Illinois, USA

Cell-mediated lysis (CML) of antigen-bearing target cells was first demonstrated in 1960, when it was shown that thoracic lymphocytes sensitized *in vivo* towards allogeneic kidney cells could, *in vitro*, lyse target cells expressing the appropriate alloantigens. This lytic activity of lymphoid cells from sensitized individuals is believed to be the correlate *in vitro* of corresponding effector functions of lymphoid cells *in vivo*. The destructive potential of lymphocytes from

immunized animals was confirmed subsequently by other investigators. Close cell-to-cell contact was found to be required between the lymphocytes and the target cells. Lysis was shown to be a rapid event which progressed as a linear function of time and depended on the concentration of effector cells. The observations suggested that a 'single hit' was required for inactivation of target cells, i.e. a single effector cell was able to destroy a target cell. These

remarkable early observations were made using model systems that involved relatively difficult and time-consuming methods of surveying target cell death.

The quantification of the lytic potential of lymphocytes was greatly facilitated by the development of convenient and sensitive assays for the measurement of target cell death, using radioactive isotopes to label target cells. One such well-defined system involved the measurement of release of radioactivity from ^{51}Cr -labeled cells lysed by immune lymphocytes. Improved culture systems made possible the detailed investigation of CML. By 1970, it was possible to generate cytotoxic murine and human lymphocytes in unidirectional mixed lymphocyte reaction (MLR). This was achieved by culturing normal lymphocytes with allogeneic lymphoid cells that had been rendered unable to divide by treatment with X-rays or mitomycin C. The reproducible populations of effector cells generated in MLR greatly facilitated the analysis of the genetic basis of CML and the investigation of the mechanism(s) of lysis. In addition, the MLR provided the fundamental techniques that enabled the derivation of clonal populations of effector lymphocytes. Homogeneous populations of lymphocytes allow specific functions to be associated with a particular cell type, providing the means to study the molecular basis for CML specificity, cell adhesion events, activation, and lytic mechanisms.

Effector cells capable of mediating lysis

With reproducible methods of generating effector cell populations and assessing target cell death, thymus-derived (T) lymphocytes were identified as the principal effector cells involved in antigen-specific CML. T lymphocytes have been divided functionally into helper T lymphocytes (T_H) or cytolytic T lymphocytes (CTLs) based on the apparent predominant function of these cells. However, recent studies indicate that there is considerable functional overlap among these populations. The capacity to demonstrate the lytic potential of a given lymphocyte population depends in part on the nature of the target cells used. Other T cell populations, whose recognition mechanisms are less well characterized than those of $CD4^+ T_H$ and $CD8^+$ CTL, are also capable of mediating lysis. These include the $CD4/CD8$ double negative $\alpha\beta$ TCR-positive T cells and the $\gamma\delta$ TCR-positive T cells.

Lymphoid cells other than T lymphocytes can also display lytic activity against certain target cells. Natural killer (NK) cells are lymphoid cells that have the capacity to lyse certain transformed target cells

such as K562 (human) or YAC-1 (murine) by a process that does not involve MHC restriction. NK activity occurs in cells having the morphology of large granular lymphocytes (LGLs); these cells express distinctive cell surface markers but they are not well defined with respect to their lineage. Natural killer lysis involves events similar to those that have been identified in antigen-specific lysis by CTLs, and may involve similar mechanisms. NK cells bear receptors for the Fc portion of immunoglobulin G (IgG); these receptors allow NK cells to lyse antibody-coated target cells by a process referred to as antibody-dependent cellular cytotoxicity (ADCC). Cells having properties that are distinguishable from those of NK cells and CTLs, termed killer (K) cells, also function as effector cells in ADCC. Finally, lytic activity can be induced in lymphoid cells in culture by exposure to supraoptimal concentrations of interleukin 2 (IL-2), which leads to the induction of lymphokine-activated killer (LAK) cells.

Properties of cell-mediated lysis

The process of CML involves the close interaction of cytotoxic lymphocytes with appropriate 'target' cells in a way that results in the unidirectional lysis of the target cell. It has been divided into several discrete stages: 1) recognition of the target cell by the effector cell, and the formation of a magnesium-dependent strong adhesion between the effector and target cells; 2) the 'programming for lysis' or 'delivery of the lethal hit'; 3) target cell lysis which does not require the continued presence of the effector cell; and 4) recycling of the effector cell.

CML is best characterized in systems involving antigen-specific T lymphocytes and, to a lesser extent, NK or ADCC effector cells. Initial cell contact between lymphocytes and target cells appears to be a random event. Once this has occurred, effector cells can form a close association or conjugate with target cells. Several cell surface structures have been implicated as mediating or contributing to cell adhesion, based on the capacity of specific antibodies to inhibit effector-target conjugation or lysis. $CD11a/CD18$ (LFA-1) and $CD2$ (LFA-2), which are expressed on lymphocytes, and $CD54$ (ICAM-1) and $CD58$ (LFA-3), which are expressed on target cells, represent adhesion molecules involved in interactions between immune cells and their targets. Other structures, including $CD8$ and $CD4$, may contribute to cell adhesion between T cells and target cells bearing class I or class II major histocompatibility complex (MHC) molecules, respectively. However, $CD4$, $CD8$ and $CD11a/CD18$ also may be involved in the regulation of signaling through the T cell receptor (TCR).

A similar role has been postulated for CD2 which reacts with CD58 expressed on target cells. Other receptor–ligand interactions are involved in the generation of CTLs from nonlytic precursors. Interactions between CD28 or the related CTLA-4 molecule on small resting T cells with CD80 (B7 or BB1) or CD86 (B70 or B7-2) on the antigen-presenting cell provide costimulatory signals for activation through the antigen receptor complex. However, CD28 costimulation does not appear to be essential for the effector phase of CTL function.

The recognitive events associated with CTL–target cell interaction is mediated through the clonally distributed TCR. In both the human and the mouse, the predominant TCR structure is that of an $\alpha\beta$ heterodimer, which has variable regions similar to but distinct from those of Ig molecules. Cells expressing the alternative, $\gamma\delta$ TCR structure have also been shown to function as lytic effector cells. The precise mechanism by which the lethal hit is triggered is not known. The TCR is physically associated on the cell surface with the CD3 complex, which has been identified as the primary structure involved in transmembrane signaling. The role of the TCR–CD3 complex in triggering the lethal hit comes from studies showing that soluble anti-TCR–CD3 monoclonal antibodies (mAbs) can inhibit lysis, while anti-TCR–CD3 mAb immobilized on the surface of target cells can induce lysis of those targets. The combination of calcium ionophore and phorbol esters (capable of activating protein kinase C) can mimic the activation via the TCR–CD3 complex. This treatment induces the release of CTL granule-associated molecules and triggers lysis of target cells nonspecifically.

Mechanisms of target cell destruction

No single mechanism seems to account for all of the events associated with target cell destruction observed in short term cell-mediated lytic assays. Membrane damage, through a process which requires extracellular calcium, has been implicated as an effector mechanism in nearly every form of CML, but the lysis of nucleated target cells also involves apoptosis. Two cell-mediated cytolytic pathways have been identified and molecularly defined. One pathway involves membrane damage inflicted on the target cell by the regulated release of pore-forming proteins by the killer lymphocyte, leading directly to the death of the target cell. A second pathway involves interaction of membrane proteins on the effector cell and the target cell which provides a signal leading to apoptosis in the target cell.

Membrane damage (perforin/exocytosis) pathway of lysis

Evidence that membrane damage may play a role in the lysis of target cells came initially from morphological studies which indicated that target cells swell and burst after contact with lymphoid cells. These observations led to the proposal that death resulted from ‘colloid osmotic’ forces due to the influx of water through the lesions. Direct evidence for the formation of ‘pores’ was provided by electron microscopy of erythrocyte ghosts following lysis by lymphocytes in an ADCC reaction, and these findings were extended to cloned CTL and NK cells. Enucleated target cells are susceptible to CML events including the release of ^{51}Cr , and anucleate erythrocytes coated with anti-TCR–CD3 mAb can be lysed by conventional CTL. Collectively, these and other data suggest that membrane damage can occur as a result of the interaction between at least some cytotoxic lymphocytes and target cells during CML. A complement component C9-like molecule, perforin, is present in the granules of CTL and NK cells. Stimuli that trigger lysis by CTL also trigger the exocytosis of granule-associated serine esterase activity. A model has been proposed in which TCR cross-linking induces the activation of protein kinase C and increased intracellular levels of calcium, which in turn leads to CTL granule exocytosis. Calcium appears to be required for exocytosis and is absolutely required for the perforin pathway. However, certain target cells can be lysed by CTL in the apparent absence of extracellular calcium or exocytosis of granular material. These findings suggested that the perforin/exocytosis pathway was not the sole mechanism of CML.

Internal disintegration (Fas) pathway of lysis

CTLs induce rapid DNA damage in target cells that is not observed in complement-mediated or perforin-mediated lysis of cells. Based on this observation, an ‘internal disintegration’ model has been proposed in which CTLs induce target cell endonucleases which digest DNA, yielding 150–180 base pair units. This process can occur in the absence of extracellular calcium.

Perforin-deficient mice have been generated using gene targeting techniques. They provide a direct assessment of the role of perforin *in vivo*. Lymphocyte development is unaffected in mice lacking perforin. Perforin-dependant cytotoxicity appears to be required to clear at least some pathogens *in vivo*. Perforin-deficient mice are unable to clear lymphocytic choriomeningitis virus, but were able to control vaccinia virus infection, although both induce strong

primary CTL responses. CTLs generated *in vivo* or *in vitro* in response to these stimuli are highly lytic toward antigen-bearing target cells that express the Fas antigen (CD95), but not against target cells which do not express Fas antigen. Studies using perforin-deficient mice have provided direct evidence for Fas-mediated pathway of lysis, which requires the expression of Fas antigen on the target cell, and involves DNA damage in target cells. The Fas ligand (FasL), is expressed on CTLs. It is currently thought that Fas-dependent cell-mediated cytotoxicity requires the interaction of the FasL on the effector cell and Fas on the target cell (perhaps inducing Fas trimerization) which triggers an, as yet poorly defined, cell death signal pathway. T cell activation can induce FasL expression, but the regulation of FasL expression is incompletely understood.

CD4⁺ as well as CD8⁺ T cells can lyse target cells bearing relevant antigen; however, not all T cells use the same lytic mechanisms. The perforin/exocytosis pathway is generally expressed by CD8⁺ CTLs and some CD4⁺ T_H2 cells, but not by CD4⁺ T cells having properties of T_H1 cells. The Fas pathway of lysis appears to be expressed by both CD4⁺ and CD8⁺ T cells.

Although perforin/exocytosis and Fas pathways seem to account for most, if not all, CML observed in short-term assays, lymphocytes produce several factors that are cytotoxic. Tumor necrosis factor α (TNF α), lymphotoxin (LT) and TNF α /LT-like molecules such as NK cytotoxic factor (NKCF) are potential effector molecules. In susceptible target cells, LT-containing supernatants produced by CTLs can induce DNA fragmentation, and LT-like molecules have been found to be associated with granules; LT-like molecules are produced by CTLs and NK, T_H and mast cells. Proteolytic enzymes have also

been implicated in the lytic activity of CTLs and NK cells and in ADCC, based on the observation that various protease inhibitors inhibit lytic activity. CTLs from mutant mice lacking the neutral serine protease, granzyme B, are able to induce ⁵¹Cr release from target cells with reduced efficiency, but are profoundly deficient in their ability to induce rapid DNA fragmentation. The role of these enzymes in lysis is not clear; however, they may be cosecreted with other granule-related molecules to induce or enhance DNA fragmentation.

Conclusion

Cell-mediated lysis is clearly a complex phenomenon that involves distinct mediators, which are either released through the process of exocytosis or are expressed on the cell surface. Those mediators which are critical to a particular form of lymphocyte-mediated lysis may depend on the type of effector cell involved and also on properties of the target cell. The identification of specific molecular mechanisms of cell mediated lysis *in vitro* should facilitate the assessment of their *in vivo* relevance.

CELL SEPARATION TECHNIQUES

Silvano Ferrini and Lorenzo Moretta, Istituto Nazionale per la Ricerca sul Cancro, Genoa, Italy

The past three decades have witnessed major progress in the development of methods allowing the identification and separation of various cell populations. This has had a major impact upon the precise dissection of the immune system and the definition of the cellular basis of the immune response. The combined use of newly identified cell surface markers and cell separation techniques has been fundamental

for the precise assignment of given functional properties to well-defined cell subsets.

The first cell separation techniques, which were developed in the early 1960s, were based on physical differences such as cell size and density. The limitation of these methods is mostly related to the low degree of physical heterogeneity existing among lymphocytes. However, this approach may be parti-

cularly useful when combined with techniques which make use of phenotypic markers to tag the cells so that they can be separated by physical means (e.g. rosetting techniques). Major advances in cell separation techniques were made possible by the identification of membrane receptors or surface antigens which are differently expressed by lymphocyte subsets. For example, the identification of immunoglobulin (Ig) molecules on the surface of B lymphocytes and of receptors for sheep erythrocytes on human T cells allowed the identification and the separation of B and T lymphocytes, respectively. More recently, the development of monoclonal antibody (mAb) technology has provided a potent tool to precisely and reproducibly identify lymphocyte subsets expressing given antigens. Most of the mAb-defined surface leukocyte antigens have been classified into a still growing list of 'cluster of differentiation' (CD) antigens. Therefore, at present, the most widely applied lymphocyte separation techniques are represented by immunoselection procedures based on the use of mAbs. Among immunoselection techniques, the use of mAbs and complement (immunotoxicity) allows the selective depletion ('negative selection') of cells expressing a given surface antigen. Other immunoselection techniques, however, allow both 'negative' and 'positive' selection. Most of these techniques are based on the attachment of antibodies to different substrates or carriers, including plastic surfaces, erythrocytes or magnetic beads. Cells that are recognized by these mAbs and thus bind to these substrates can be subsequently separated by adherence, density gradients or magnetic fields, respectively. There is little doubt that the most precise and objective tool for the separation of cells stained with fluorochrome-labeled mAbs is represented by the fluorescence-activated cell sorter (FACS). A major advantage of FACS fractionation over the other immunoselection procedures is represented by the possibility of precisely defining the density of a given surface antigen and, therefore, the threshold values for cell separation. In addition, the FACS allows simultaneously analysis of several parameters and the separation of cells accordingly. In spite of these major advantages, a limitation of the FACS is related to the relatively low numbers of cells that can be processed per unit of time.

When approaching a problem of lymphoid cell separation, the choice of the technique to be applied should take into account a number of parameters, including cell numbers, purity and yield. In most instances, cell purity is inversely related to the yield. Less purity should also be expected when the cells of interest represent a minor fraction of the initial population. In addition, the possible consequences of

cell manipulations on sterility, cell viability and function should be carefully considered. In some instances it may be convenient to combine two methods, for example a rosetting technique (which allows the processing of large numbers of cells) followed by FACS sorting (to obtain a high degree of purity).

The principal methods of lymphoid cell separation are listed in Table 1 and are described below.

Techniques based on physical properties of the cells

The two procedures that have been most widely applied for lymphocyte separation based on physical differences are sedimentation separation and density gradient separation.

In *sedimentation separation* (or velocity sedimentation), cell suspensions are stratified in a thin layer on top of a fluid column contained in appropriate sedimentation chambers. Cells are allowed to sediment through the fluid under the action of gravitational forces (1g sedimentation). Alternatively, to speed up the procedure, larger forces can be applied by the use of centrifugation. To this end, a special device has been developed, the centrifugal elutriator, which allows the purification of larger numbers of cells within a short time. In sedimentation separation, cells are fractionated primarily on the basis of differences in size, while the cell density has a minor influence on the sedimentation rate. After appropriate time intervals cell fractions can be collected through the bottom of the sedimentation chambers. Clearly, cells collected first are those of a larger size.

Techniques based on *density gradient separation* are widely employed and many different procedures have been developed. These techniques are based on the preparation of gradients of appropriate density which may be either discontinuous or continuous. In principle, the material composing the gradient should be nontoxic for the cells. In the case of continuous gradients, cells are usually layered on top of the gradient (in some instances, however, it may be convenient to load cells on the bottom, or disperse them within the gradient). The range of densities of the gradient should cover the densities expected for the cells of interest. The gradient is centrifuged for a time sufficient to allow cells to reach an equilibrium in the portion of the gradient corresponding to their density. Cells of density greater than that of the gradient will sediment at the bottom of the tube. For lymphoid cell separation it should be noted that the differences in density among cell subsets are small, ranging between 1.05 and 1.10 g ml⁻¹. The materials originally employed for continuous density gradients

Table 1 Principal methods of cell separation

<i>Principal</i>	<i>Method</i>	<i>Applications</i>
Physical differences	Sedimentation Density gradient centrifugation	Cell separation according to size Cell separation according to density
Functional properties	Adhesion to plastic Adhesion on nylon wool columns Phagocytosis of iron particles 'Hot' thymidine pulse Selective cell stimulation and growth	Positive or negative selection of macrophages Isolation of T lymphocytes Depletion of macrophages Depletion of proliferating cells Enrichment of proliferating cells
Expression of surface receptors	E (erythrocyte) rosettes EA (erythrocyte-antibody) rosettes EAC (erythrocyte-antibody-complement) rosettes	Positive or negative selection of T cells: Fc γ -receptor ⁺ cells Complement receptor ⁺ cells
Expression of surface antigens (immunoselection)	Immunotoxicity (complement depletion) Immunoaffinity columns Immunoadherence (panning) Rosetting with antibody-coated erythrocytes Immunomagnetic beads Immunofluorescence and FACS fractionation	Depletion of cells expressing a given surface antigen Negative or positive selection of cells expressing a given surface antigen

included bovine serum albumin (BSA) and, more recently, colloidal silica. In discontinuous density gradients, which may be either single or multiple step, cell suspensions are layered on the top of the gradient and centrifuged until equilibrium is reached. Cells will not move into the portion of the gradient having a higher density than that of the cells and will thus accumulate at the interface. The most widely used materials for discontinuous gradients are Ficoll-Hypaque, BSA or colloidal silica. The Ficoll-Hypaque solution used for human lymphocyte separation is an isotonic solution of sodium metrizoate and Ficoll with a density of 1.077 g ml^{-1} . Ficoll-Hypaque gradients are primarily used for the isolation of mononuclear cells (lymphocytes and monocytes) from blood and for the isolation of lymphocytes forming rosettes with erythrocytes. Diluted blood (1:2–1:4) is layered on the top of Ficoll-Hypaque and then spun on a centrifuge. After a suitable time interval, mononuclear cells can be collected at the interface, while erythrocytes and neutrophils are found at the bottom of the tube. Percoll is a commercially available solution composed of colloidal silica coated with polyvinylpyrrolidone in order to render the material nontoxic for cells. Percoll is characterized by high density (1.130) and low osmolality; as a consequence, for the preparation of Percoll density gradients for cell separation, the osmolality is adjusted to physiological values by mixing 9 parts of Percoll solution with 1 part of $10\times$ saline. Percoll solutions with different densities can be easily obtained by appropriate dilutions in isotonic

medium, thus allowing the preparation of multiple step discontinuous gradients; these are particularly useful for the isolation of different subsets of lymphocytes characterized by density differences (e.g. isolation of 'large granular lymphocytes' (LGL) from a lymphoid suspension or isolation of activated blasts from resting lymphocytes).

Techniques based on functional properties of the cells

Adhesive or phagocytic properties

Certain mononuclear cell types have the property of adhering to plastic surfaces and/or to nylon wool. Thus, cells of the monocyte/macrophage lineage rapidly (30–60 min) adhere to plastic when incubated at 37°C . This property has been widely exploited for both positive and negative selection of monocytes from peripheral blood-derived mononuclear cells. The preferential ability of monocytes and B lymphocytes to adhere to nylon wool columns has been frequently applied to remove these cells from mononuclear cell suspensions and, thus, to enrich for T lymphocytes. The demonstration that subsets of interleukin 2 (IL-2)-activated effector cells capable of lysing fresh tumor cells (i.e. lymphokine-activated killer (LAK) cells) display the ability to adhere to plastic (adherent LAK) has provided a useful tool for enriching for these cells. Another method frequently employed for removal of monocytes is based on the fact that monocytes display phagocytic properties:

cells that have ingested iron particles (carbonyl iron) are removed by application of a magnetic field.

Selective depletion of cells undergoing proliferation

Lymphocytes undergoing proliferation induced by antigens or mitogens actively incorporate ^3H -thymidine [^3H]TdR and their DNA. Beside the conventional measurement of cell proliferation, [^3H]TdR with a higher specific activity can be used to induce selective killing of proliferating cells. If the amount of [^3H]TdR incorporated in the cDNA is sufficiently high, intranuclear irradiation due to β -particle emission will result in cell death. The addition of cold TdR will prevent further incorporation of [^3H]TdR. This technique allows, for example, the selective elimination of T cells proliferating in response to soluble antigens or alloantigens. An alternative procedure is based on the use of 5-bromodeoxyuridine (BrdU) followed by exposure of cells to ultraviolet (UV) light. When activated by UV light the BrdU incorporated into the DNA of proliferating cells will cause breaks in the DNA, resulting in cell death.

Selective cell stimulation and growth

Another approach to the selection of given lymphocyte populations is based on the ability of these cells to respond selectively to appropriate mitogenic stimuli in culture. For example, superantigens or mAbs specific for a given TCR- V_β will induce a selective activation and proliferation of T cells expressing the appropriate V_β . In addition, the use of recombinant cytokines acting as growth/differentiation factors may induce the preferential expansion of given subsets. For example, IL-4 will induce a preferential growth/differentiation towards T_H2 cells. On the other hand, peripheral mononuclear cells, in the presence of both IL-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF) will lead to proliferation and differentiation of immature dendritic cells, which can be induced to a more mature phenotype by subsequent addition of, for example, tumor necrosis factor α .

Rosetting techniques

Rosetting techniques are widely employed in immunology for the detection or purification of cells expressing a given surface 'receptor' of antigen. The principle of this separation technique is the formation of cell agglutinates (rosettes) with a consequent change in size or density of the rosetting cells with respect to nonrosetting cells. A common approach is the use of erythrocytes which spontaneously bind to

certain lymphocyte subsets (e.g. sheep erythrocytes binding to human T cells via CD2 surface molecules). Other erythrocytes which do not spontaneously bind to human lymphocytes can be coated with appropriate ligands or mAbs which allow binding to specific receptors or surface antigens. Whatever the rosetting technique employed, the cell suspension containing rosetting cells can be subjected to either sedimentation or, more frequently, density gradient separation. Rosettes formed with erythrocytes can be easily separated from nonrosetting cells by Ficoll-Hypaque gradients and recovered from the bottom of the gradient. Rosetting cells can be freed from erythrocytes by lysis in appropriate buffers containing ammonium chloride or using distilled water.

Immunoselection techniques

These techniques make use of antibodies (either polyclonal antisera or preferably mAbs) directed to surface antigens expressed by given lymphocyte subsets. Both direct and indirect immunoselection procedures have been applied. Direct methods require a single step (i.e. only the antibody directed to a relevant antigen is needed), while indirect methods require a second reagent (i.e. an antiserum directed to the first antibody). The advantages of direct methods include a greater speed and a better specificity, since possible reactions of the second (anti-Ig) reagent with cell surface antigens are avoided. However, indirect methods may be preferable due to their sensitivity (amplification given by the second antibody) and the use of less reagent (e.g. mAbs). In addition, indirect procedures may be more convenient when several different first-step antibodies requiring a common second reagent are used.

Immunotoxicity

In these procedures, antibodies are used as a means to induce selective cytolysis of cells expressing a given antigen at the cell surface. This can be achieved either by coupling mAbs to cytotoxic reagents (immunotoxins) or by the addition of complement. These procedures (particularly the complement depletion that has been widely applied in both basic and clinical immunology) have the major advantage that large numbers of cells can be processed. For example, complement depletion has been used in *in vitro* studies aimed at establishing whether a given function is associated with a phenotypically defined cell subset. It should be noted that the inhibition of a cell function following depletion of a lymphocyte subset may be consequent either to the elimination of cells directly responsible for that function or to removal of cells with a regulatory role on the func-

tion itself. An important clinical application of complement depletion has been the removal of T lymphocytes from bone marrow prior to allogeneic transplantation. Both polyclonal antisera and mAbs can be used as a source of antibody to be used in complement depletion. However, not all antibody isotypes are capable of complement fixation and this should be taken into account when using mAbs: only murine IgM, IgG2a and IgG2b work in this procedure. Regarding the source of complement, rabbit or guinea pig serum is routinely used, either fresh, lyophilized or stored at -80°C . It should be stressed that sera may contain 'natural' antibodies reacting with the cells of interest, thus leading to complement activation and cell lysis even in the absence of test antibody. This problem must be avoided by carefully selecting sera on the basis of low 'natural' antibody titers. In addition, natural antibodies (e.g. antihuman) can be removed by adsorbing sera with appropriate cells (e.g. human erythrocytes) at 4°C . The procedure for complement depletion involves a first step in which cell suspensions are incubated for 30–60 min at 4°C with an appropriate dilution of the relevant antibody. Subsequently, cells are washed and, after the addition of appropriate amounts of complement, they are incubated at 37°C for at least 1 h. The first step (binding of antibody to cells) must be carried out at low temperature in order to avoid antibody-mediated surface antigen capping and modulation, which would prevent optimal complement fixation and cell lysis. An approximate estimation of the efficiency of cell lysis can be obtained by dye-exclusion viability tests (e.g. trypan blue). Dead cells can be further removed by density gradient separation.

Immunoadhesion

In these procedures, antibodies directed to cell surface antigens are bound to a solid support, so that cells expressing the relevant antigen can be easily separated by adherence to the support itself. The solid support is represented by either plastic surfaces (e.g. Petri dishes) or beads. The latter have been used to prepare immunoaffinity columns for cell separation. These columns have been primarily employed for negative selection of cell populations, as the recovery of cells sticking to the columns is difficult and results in poor cell yield and viability. In contrast, immunoadherence to plastic surfaces (panning) allows both positive and negative cell selection. Attachment of the antibody to the solid support can be achieved either by a chemical covalent link or by physical adsorption on appropriate hydrophobic plastic surfaces. In the case of panning, the antibody ($5\text{--}50\text{ }\mu\text{g ml}^{-1}$) can be easily attached to untreated

polystyrene Petri dishes by adsorption using alkaline buffers (e.g. 50 mM TRIS pH 9.5). After overnight incubation the unbound antibody is washed out and free adsorption sites of the plastic are saturated by incubation with a protein solution (e.g. BSA or fetal calf serum, FCS). For lymphocyte fractionation, cell suspensions are layered in a small volume on Petri dishes and incubated at 4°C in the presence of low protein concentration (e.g. 2% FCS) for 1 h. Incubation at low temperature is required in order to prevent nonspecific binding of cells to the plastic. The occurrence of cell adherence to Petri dishes during the procedure can be conveniently checked by microscopic examination. At the end of the incubation period, the nonadherent cells are gently removed by pipette, followed by washing. The adherent cells, expressing the relevant antigen, are recovered after vigorous pipetting or by scraping with a 'rubber policeman' (a rubber-covered glass rod).

Immunomagnetic beads

In this immunoselection technique, antibodies are attached to iron-containing microspheres ($2\text{--}5\text{ }\mu\text{m}$ diameter). Polystyrene microspheres obtained by polymerization in the presence of colloidal iron are now widely employed. The antibody is attached to the beads either by physical adsorption or by chemical covalent links. Either antibodies directed to relevant cell surface antigens or anti-Ig (second) antibodies can be linked to the beads for direct or indirect separation techniques, respectively. In the first approach, the cell suspension is allowed to interact directly with the microspheres; in the indirect approach, lymphocytes are first stained with the relevant mAb and subsequently mixed with the anti-Ig covered beads. In both cases, antigen-positive cells will form rosettes with the beads. Rosetting cells can be easily separated from other cells by applying a magnetic field for a short time (1–2 min). Both negatively and positively selected cells can be utilized for further analysis or cell culture. In general the magnetic bead:lymphocyte ratio should be higher in the case of negative selection. Release of magnetic beads from rosetting cells can be achieved by 24–48 h incubation of cells at 37°C or by the addition of an excess of soluble antibody, displacing the beads-bound antibody. Free beads can then be removed by magnetic separation. Magnetic beads have been successfully used both for fractionation of lymphoid subsets and for 'purging' bone marrow to remove tumor cells or T lymphocytes prior to transplantation.

Magnetic cell sorting

Magnetic cell sorting represents an interesting evolution of immunomagnetic separation techniques. The

principle is based on the use of mAbs or other ligands (e.g. lectins) which specifically bind to surface antigen/receptor expressed by a given cell subset. These reagents are labeled with microbeads (5×10^2 -fold smaller than eukaryotic cells). The cell suspension treated with the magnetically-labeled mAbs are passed through a separation column which is placed in a potent magnetic field. Unlabeled cells pass through the column and can be collected at the bottom, while labeled cells are retained on the column. In order to recover the labeled subset of cells the column is removed from the magnetic field, thus permitting the labeled cells to be eluted from the column. Both direct or indirect labeling can be used with this technique and it is possible to separate a relatively large number of cells in a short time.

Separation by fluorescence-activated cell sorter (FACS)

Flow cytofluorimetry has provided a precise and objective means of quantifying both the number of cells expressing a given surface marker and the extent to which the marker is expressed. By combining this technology with mAbs directed to lymphocyte surface antigens it is now possible to define and purify lymphocyte subpopulations with a precision that was not possible using other methodologies.

Lymphocytes to be analyzed and/or separated by FACS must be labeled with fluorochrome-conjugated antibodies using either direct or indirect immunofluorescence techniques. The FACS allows purification of both antigen-positive/negative subsets and also allows the definition and separation of subsets on the basis of multiple parameters.

CELL SURFACE MOLECULES, IMMUNOPRECIPITATION OF

Frank AW Verreck and **Frits Koning**, Department of Immunohepatology and bloodbank, University Hospital Leiden, Leiden, The Netherlands

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Immunoprecipitation of cell surface molecules is a quick and reliable method that allows the analysis of cell surface expressed molecules recognized by monoclonal antibodies and by antisera. In addition, using proper solubilization techniques, interactions between cell surface expressed molecules can be defined that give insight into subunit interactions in multichain receptor complexes. Usually lysates of cell surface iodinated cells are used. The principle of immunoprecipitation is based on 1) solubilization of membrane proteins by the use of nonionic detergents, 2) subsequent interaction of specific antibody with the solubilized membrane antigen, and 3) recovery of the antibody-antigen complexes by binding to an insoluble support, thereby allowing washing procedures to remove unbound molecules. Analysis of such immunoprecipitates usually takes place by SDS-PAGE or isoelectric focusing (IEF).

Solubilization of membrane molecules

The most widely used detergents for membrane solubilization are the nonionic detergents Triton X-100 and NP40 that have almost identical properties. Typically, $1-10 \times 10^7$ cells are resuspended in 0.5–1 ml of the following buffer: 50 mM Tris-HCl, 150 mM NaCl, 5 mM EDTA, 10 mM iodoacetamide, pH 8, containing either 0.5–1% Triton X-100 or NP40 and the following protease inhibitors: leupeptin, antipain, chymostatin, pepstatin (all $1 \mu\text{g ml}^{-1}$) and 0.1 mM 4-(2-aminoethyl)-benzenesulfonylfluoride (AEBSF), and lysed at 0°C for 30 min. Insoluble material is subsequently removed by centrifugation at 13 000 g for 15 min.

As an alternative to NP40 and Triton X-100 the nonionic detergents CHAPS (5 mM final concentration) or digitonin (1% final concentration) can be used in the lysis buffers. CHAPS and digitonin share the property that, in contrast to NP40 and Triton X-100, they do not, or hardly, disrupt subunit interactions within multichain receptor complexes like the T cell receptor, thereby allowing the recovery of more intact receptor complexes.

Immunoprecipitation

For immunoprecipitation, the antibodies used to detect the antigens must be bound to an insoluble ligand either before or after binding to their target antigen in order to facilitate washing procedures. For this purpose there are a number of alternatives: either the antibodies are covalently coupled to Sepharose beads or they are bound to Sepharose beads that have been coated with protein A or anti-immunoglobulin (Ig) antisera. It is also possible to use fixed *Staphylococcus aureus* bacteria, that express the protein A on their cell surface. Since at pH 8 protein A binds to the large majority of mouse, rabbit and human derived Ig types (not IgM), Sepharose protein A is a very convenient reagent to immobilize many antibodies used for immunoprecipitation. Before specific immunoprecipitations are carried out, the lysates are precleared to remove non-specifically binding material by adding 100 μl Sepharose protein A beads and 75 μl normal rabbit serum to 1 ml lysate, followed by gently shaking at room temperature for 2 h. After removal of the beads, specific immunoprecipitations are carried out by mixing 1–10 μl monoclonal antibody or antiserum and 100 μl lysate for 60 min, either at room temperature or at 4°C , followed by the addition of 10 μl Sepharose protein A beads. After an additional 60 min, the beads are spun down (30 s, 13 000 g) and washed four times with 0.5 ml lysis buffer before analysis. This methodology can be easily modified for the use of immobilizing reagents other than Ig.

Sequential immunoprecipitation

Many cell surface expressed antigens are multichain complexes in which the chains may or may not be held together by disulfide bridges. The question may arise as to which chain in such complexes is actually recognized by the antibody or antiserum studied. Depending on the presence or absence of a disulfide bridge, one of the following procedures may be used to answer this question. Absence of a disulfide bridge: a normal immunoprecipitate is resuspended in 0.5% SDS and boiled for 3 min. This treatment leads to the dissociation of the individual chains and to the destruction of the antibody used as immunoprecipitating reagent. Subsequently, the SDS is

neutralized by the addition of three volumes of lysis buffer containing 1.5% NP40. This preparation is now used for immunoprecipitation with the antibody of interest. Part of the preparation can be analyzed directly. Comparison of the bands present in the original and in the reprecipitated material indicates which molecule is actually recognized by the antibody. Presence of a disulfide bridge: the immunoprecipitate is resuspended in a 0.5% SDS solution containing 2 mM DTT and boiled for 3 min to reduce the disulfide bridge and dissociate the individual chains. Subsequently the material is alkylated by the addition of 10 mM iodoacetamide. The remaining procedure is as described above.

Cross-linking

Biochemical cross-linkers are available that are reactive with lysine residues and, as these cross-linkers have two reactive groups, they can generate covalent, thiol-cleavable bonds between cell surface molecules that are in close vicinity to each other ($<13 \text{ \AA}$). They can thus be used to study the spatial relationship between cell surface expressed molecules. The most commonly used cross-linker is DSP (dithiobis (succinimidylyl propionate)). For cross-linking, cells are resuspended in 0.5 ml PBS containing 1 mM MgCl_2 , 0.02% NaN_3 . Subsequently 50–100 μg DSP is added (5–10 μl of 10 mg DSP per ml DMSO) and the mixture is incubated on a shaker at room temperature for 30 min. Then the cells are washed twice with PBS and lysed. Subsequently immunoprecipitates can be obtained from these lysates as described above. Analysis of such immunoprecipitates under both reducing and nonreducing conditions by SDS-PAGE indicates which molecules are cross-linked by the DSP treatment.

Bulk purification of molecules of the major histocompatibility complex

Since the recent insight into the molecular basis of peptide presentation by molecules of the major histocompatibility complex (MHC), the bulk purification of peptide-MHC complexes has become established as a standard technique. It is now widely used in order to identify natural peptide ligands or peptide-binding characteristics of particular MHC specificities. In principle, this purification method can be considered as a large-scale immunoprecipitation procedure, which can be adapted for the bulk purification of any cell surface molecule.

The isolation of MHC-bound peptides

The MHC-peptide complexes are purified from cells of which pellets are collected at -70°C . A lysate (of 10^{10} cells or more) is made by thawing and resuspending the cell pellet at a concentration of 2×10^8 cells ml^{-1} in NP40-containing lysis buffer (described above). The lysate is precleared by incubation with Sepharose CL-4B beads (10 ml beads per 50 ml lysate; Pharmacia). This incubation can be done batch-wise in 50 ml tubes under quiet agitation for 2 h at room temperature. After the incubation the Sepharose beads are removed from the lysate using a glass filter that is placed over a vacuum. The precleared lysate is subsequently incubated batch-wise for 16 h at 4°C with CNBr-activated Sepharose CL-4B beads to which antibody specific for the MHC molecule of interest has been covalently coupled (according to manufacturer's guidelines; Pharmacia). Then the affinity beads are washed on a glass filter (placed over a vacuum), taking care not to disturb the homogenous gel bed on the filter or letting the bed run dry. First, the beads are washed with minimally 5 bed volumes of a buffer containing 50 mM TRIS, 150 mM NaCl, pH 8.0, to which 0.5% NP40 (v/v; HPLC grade) has been added and subsequently with minimally 10 bed volumes of the TRIS/NaCl buffer without NP40. Then washing proceeds with 10 bed volumes 10 mM TRIS buffer, pH 8.0, and the beads are transferred and packed into a disposable column. The MHC-peptide complexes are eluted from the affinity beads with 3 bed volumes 10% acetic acid or 0.1% trifluoroacetic acid. The high molecular weight chains of the MHC molecules are removed from the eluate by ultracentrifugation over a membrane filter with a 10 kDa cut-off (Centriprep 10, Amicon). The ultimate peptide sample is concentrated by evaporation under vacuum and is ready for further processing.

The isolation of MHC molecules

In order to isolate intact MHC molecules for the purpose of (peptide) binding analyses, the procedure to follow is identical to that described for the isolation of MHC-bound peptides, except for the use of different buffers in the washing procedure and the elution of MHC under basic rather than acidic conditions. Briefly, the affinity beads that have been incubated with the precleared lysate are washed on a glass filter using the following buffers: minimally 5 bed volumes of TRIS/NaCl buffer (see above) with 0.5% NP40, 10 bed volumes of TRIS/NaCl buffer without NP40 and minimally 10 bed volumes of TRIS/NaCl with 0.4% (w/v) *n*-octylglucoside. In the latter buffer the beads are transferred to a disposable column and the

MHC complexes are eluted with 3 bed volumes of 50 mM diethylamine, 150 mM NaCl, 0.4% (w/v) *n*-octylglucoside, pH 11.5. The eluate can be neutralized using a 2M glycine solution (pH 2.5) and the high molecular weight MHC complexes in the eluate can be retained in a small volume after ultracentrifugation over a membrane filter (10 kDa cut-off).

CELL SURFACE RECEPTORS AND ADHESION MOLECULES, THREE-DIMENSIONAL STRUCTURES

Jürgen Bajorath, Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, Washington, USA

The extracellular regions of immune cell surface proteins consist of one or more protein domains. These domains are often independent folding units which can be expressed in soluble form and subjected to structural analysis. Since 1990, more than 30 three-dimensional structures of immune cell surface proteins have been determined. These include single or multiple domains of adhesion molecules, receptors, and a few receptor–ligand complexes. The studies have provided structural prototypes of cell surface protein superfamilies. The structural basis of cell adhesion, specific receptor–ligand interactions, and ligand-induced receptor oligomerization is beginning to be understood.

Cell surface proteins of the immune system

In recent years, significant progress has been made in understanding the three-dimensional structures of proteins which are expressed on the surface of immune cells. Table 1 lists 35 structures of such proteins (major histocompatibility complex molecules are not discussed here). Smaller domains have often been studied using nuclear magnetic resonance (NMR) methods. The larger and more complex structures have been determined by X-ray crystallography.

A large number of immune cell surface proteins include a single transmembrane region, and their extracellular binding domains are relatively inde-

pendent from the membrane. Thus, soluble extracellular fragments suitable for structural studies can be obtained in many cases. This is in contrast to, for example, G protein-coupled receptors of the nervous system. These receptors traverse the membrane seven times, and the ligand binding sites are more intimately associated with transmembrane segments and difficult to isolate.

Modular arrangement of extracellular regions and protein superfamilies

The extracellular regions of immune cell surface proteins include distinct domains which are often connected to the transmembrane domain by a linker or stalk region. Only one or two domains may have specific binding functions. Others may trigger oligomerization or ensure that binding domains are sufficiently distant from the membrane. Many extracellular protein modules belong to superfamilies. By definition, members of protein superfamilies share limited sequence similarity, often 30% or less, but similar three-dimensional structures. Table 1 includes structural prototypes of superfamilies determined to date. Some small domains found in different cell surface proteins consist of β sheets or hairpins which may be arranged sandwich-like and stabilized by disulfide bonds.

The immunoglobulin superfamily (IgSF): variations of a common fold

Many of the leukocyte-specific cell surface proteins characterized to date include immunoglobulin (Ig) domains or closely related structures. The Ig fold, as seen in antibody structures, is a tightly packed sandwich of two antiparallel β sheets of four and three (constant, C) or four and five strands (variable, V), respectively, which are connected following conserved topology. In V domains, the sheets are formed by strands ABED and GFCC'C'', respectively. In C domains, the C' and C'' strands are absent. A canonical disulfide bond covalently links the sheets. The N- and C-termini are on opposite sides of the domain, thereby permitting Ig domains to form linear arrays.

Structural studies on Ig-like domains have revealed variations of the Ig fold. For example, the length of β strands and the spatial positions of strands at the edges of the sheets vary. The N-terminal (A) strand is often split into A and A' strands which hydrogen bond to different sheets. Strands may completely switch from one sheet to the other and thereby change the topology of the structure. Furthermore, the length and conformations of loops connecting the sheets are variable. The canonical disulfide bond is absent in some structures and other disulfide bonds may be present. On the basis of sequence and structure comparison, IgSF domains have been classified as, for example, V, C1 or C2 (related by a strand switch), I (intermediate between V and C), or A (V variant where the C'' strand switches the sheet)

domains. V domains often include (part of) the binding site in IgSF cell surface proteins. Only a few examples of V domain-mediated interactions have been studied in detail. The (A')GFCC'C'' face appears to be the center of interactions studied so far, irrespective of the molecular nature of the ligand.

Structures of IgSF cell surface receptors and related proteins

Figure 1A shows examples of IgSF cell surface receptor structures. The extracellular region of CD8 includes a single V domain which dimerizes like the variable light and heavy chains of an antibody. The structure of a CD8/MHC class I complex shows that residues in Complementarity Determining Region (CDR)-like loops and β -strands of the CD8 homodimer contact the $\alpha 2$ -, $\alpha 3$ -, and $\beta 2$ -microglobulin domains of MHC class I. The extracellular regions of CD4 and CD2 are stable as monomers and include four and two IgSF domains, respectively. In both structures, an N-terminal V-like domain is followed by a C2 domain. In CD4, a continuous β strand connects the first and second domain which form an extensive and rigid interface. This structure is very similar to the structure including the third and fourth domain of CD4. Structures of CD4 including all four extracellular domains in different crystal lattices reveals that domains 2 and 3 are more flexibly connected. In CD2, the two domains are connected by a linker and the interface is less extensive. Despite

Figure 1 Cell surface proteins of the IgSF and related molecules. Structures are represented as α traces. N- and C-termini are labeled. (A) Three IgSF members: CD8, CD4 and CD2. (B) Structure of a four-domain fragment of fibronectin. The three-dimensional structure of FN type III is similar to IgSF C domains.

these differences, the relative orientation of the two domains is similar in CD4 and CD2.

Structures of a V_α domain and β chain of different TCRs, a complete mouse TCR (and its preliminary complex with MHC class I), and a human TCR/MHC class I complex have been reported. These structures confirm the structural similarity of antibodies and TCRs. In the V_α domain, which forms a tetramer of homodimers, the C' strand switches the sheet, a departure from V domain structure (see above). The β chain includes a V and a C domain which form an extensive interface (two to four times larger than in antibody structures). Overall, the mouse and human TCR structures are similar. In the mouse TCR structure, the $C\alpha$ domain, which is disordered in the human TCR, substantially departs from known IgSF structure types. In the structure of the complex with peptide-bound MHC class I, the TCR binds with its CDR-like loops diagonally across the composite MHC/peptide surface. The orientation is such that the $V\alpha$ CDR loop 1 contacts the N-terminal and the $V\beta$ CDR loop 3 the C-terminal region of the peptide.

In Figure 1B, a structure consisting of four fibronectin (FN) type III domains is shown. FN type III domains are structurally similar to C2 domains, but are not included in the IgSF. Their structure is a sandwich of a four-stranded and a three-stranded β sheet. The domain lacks the Ig disulfide bond, and the packing of its hydrophobic core is distinct from the IgSF. FN type III domains are found in extracellular matrix proteins and in cytokine receptors. Domain 10 of fibronectin includes an RGD sequence in a loop and is therefore an integrin ligand and

implicated in cell adhesion. Although the structures of single FN type III domains are very similar, their domain interfaces are not conserved. The two central domains display a relative orientation similar to CD4 and CD2.

Cadherins, also distantly related to the IgSF, are homophilic and calcium-dependent adhesion molecules. Like fibronectin, cadherins may include ten or more extracellular domains. The interfaces between domains are stabilized by calcium binding which also supports dimerization of cadherin domains. Crystal packing has suggested different ways in which cadherins interact. On the basis of crystal lattice interactions, models have been proposed for the formation of network-like multivalent cellular adhesion interfaces.

Structures of leukocyte and endothelial cell adhesion molecules

In the course of an inflammatory response, leukocytes are recruited to activated vascular endothelium by adhesion interactions of increasing strength. Selectins are responsible for the initial low avidity (protein/carbohydrate) interactions. Firm adhesion is achieved by high avidity (protein/protein) interactions between leukocyte integrins and their endothelial ligands. Structures of binding domains of key molecules have been determined and are shown in Figure 2.

The X-ray structure of E-selectin includes an N-terminal calcium-dependent (C-type) lectin domain which is followed by an EGF-like domain. The C-type lectin fold, first observed in the structure of rat

Figure 2 Binding domains of adhesion proteins. Structures are represented as α traces, and the N- and C-termini are labeled. E-Selectin includes two (C-type lectin and EGF-like) domains. The circle indicates the position of a conserved calcium ion. The I domain of Mac-1, a β_2 -integrin, is shown. The circle indicates the position of the MIDAS motif (see text). The structure of VCAM-1, a β_2 -integrin ligand, includes two Ig domains (see also Figure 1).

mannose-binding protein, includes extended regions of unusual secondary structure in the vicinity of a highly conserved calcium-binding site. In the mannose-binding protein, this calcium is directly involved in carbohydrate binding. A similar role has been proposed for the conserved calcium in E-selectin, but the structure of a complex between E-selectin and its carbohydrate ligand remains to be determined.

The ligand binding domain of the β_2 -integrin Mac-1 (CD11b/CD18) adopts a dinucleotide-binding (Rossmann) fold which consists of a hydrophobic parallel β sheet covered by amphipathic α helices on both sides. The Mac-1 structure includes an Mg^{2+} -binding site which topologically corresponds to the active site in dinucleotide cofactor-binding enzymes. The cation coordination sphere is open and, in the crystal, completed by a negatively charged residue from a neighboring molecule. This site has been termed the metal ion-dependent adhesion site (MIDAS motif) and is thought to be directly involved in ligand binding. Structural analysis of an Mn^{2+} -bound form of Mac-1 has revealed conformational changes, compared to the original structure.

The structure of ICAM-1, the Mac-1 ligand, is unknown, but the structure of the related VCAM-1 has been determined. This structure includes two of seven IgSF domains which form VCAM-1's extracellular region. A terminal IgSF I domain is followed by a C2 domain, and the domain interface is reminiscent of CD2. The conserved integrin-binding sequence (QIDSPL) resides in the CD loop of the I domain. The aspartic acid is thought to complement

the MIDAS motif. The interaction involves surface regions proximal to the shared cation-binding site.

Structures of cell surface receptor-ligand complexes

The structures of several receptor-ligand complexes have also been reported (see Table 1). For immune cell surface receptors, ligand-induced receptor oligomerization is a major determinant of signal transduction. Figure 3 compares the structures of the complexes involving human growth hormone (hGH) receptor (hGHR) and the 55 kDa tumor necrosis factor (TNF) receptor (TNFR).

The prototypic fold of the TNFR/nerve growth factor receptor superfamily (Figure 3A) consists of stacked elongated domains. These domains have a very limited hydrophobic core and are stabilized by conserved disulfide bonds in a ladder-like arrangement. TNFR includes four domains, but only domains 2 and 3, which contact ligand, are well ordered in the X-ray structure. In contrast, the TNF fold consists of an antiparallel β sandwich with jelly-roll topology. Three monomers form a threefold symmetrical trimer. Three symmetry-related receptor-binding sites are formed at the interfaces between the TNF monomers. The receptor binds roughly parallel to the threefold axis, and the bound receptors do not contact each other. Thus, ligand binding leads to TNFR trimerization. Structures of free TNF and TNFR have shown that neither ligand nor receptor undergo significant conformational changes upon binding. In the crystal of uncomplexed TNFR,

Figure 3 Cell surface receptor-ligand complexes. Structures are represented as backbone traces (receptors, thick lines; ligands, thin lines). (A) The TNF β /TNFR complex. From left to right: TNFR, a TNF subunit, trimeric TNF, and the TNF/TNFR complex. (B) hGH/hGHR. From left to right: hGHR, consisting of two FN type III-like domains (see also Figure 1), hGH, and the hGH/hGHR complex.

dimeric forms were observed which, if present on the cell surface, may stabilize an inactive state of TNFR in the absence of ligand.

Figure 3B shows the structure of the hGH/hGHR complex. The receptor consists of two FN type III domains, and the ligand displays a four helix bundle fold. The hGHR architecture is shared by other cytokine receptors including the human prolactin receptor (hPRLR), the interferon γ receptor (IFN γ R α) and tissue factor (TF), but the relative orientations of the FN type III domains differ. Binding of hGH to its receptor leads to receptor dimerization. In contrast to TNF/TNFR, the binding sites in the hGH/hGHR complex are not equivalent, and the bound receptors contact each other. The hGH/hGHR interaction is asymmetrical in the sense that the receptors bind to different sites of the ligand. The complex forms sequentially. First, a high affinity 1:1 complex is formed, then a second receptor is engaged in the interaction. The binding of the second receptor is stabilized by receptor-receptor interactions. hGH also binds to hPRLR, and the structure of a 1:1 (high-affinity) hGH/hPRLR complex has been determined. This interaction is made possible in part by changes in the relative domain orientation of hPRLR compared to hGHR.

The erythropoietin (EPO) receptor is also structurally similar to hGHR but dimerizes in a somewhat different orientation when complexed with an agonist peptide. In contrast to hGH, IFN γ is an intertwined helix bundle homodimer. Two equivalent receptor-binding sites are presented which correspond to the high-affinity site in hGH. In the structure of the complex, receptors are bound at twofold symmetry-related sites and are separated by ~ 27 Å. Tissue factor binds a structurally distinct ligand, blood coagulation factor VIIAa, in a 1:1 complex. The TF region involved in binding differs topologically from the binding sites in hGHR. The interleukin (IL)-1 receptor consists of three extracellular Ig-like domains and binds IL-1 β (and an antagonist) involving regions not corresponding to those in other cytokine receptors.

The structure of the rat neonatal Fc receptor (NFCR), responsible for binding maternal IgG, is very similar to MHC class I. However, the helices corresponding to the MHC peptide-binding site move together and essentially close the groove. A low-res-

olution structure of NFCR in complex with an Fc fragment has shown that the Fc-binding site does not correspond to the MHC peptide-binding site. Rather, the Fc fragment binds to the side of the receptor. The NFCR/Fc complex provides an instructive example of how similar structures can mediate distinct binding functions.

Characteristics of the organism and its antigens

Life cycle of *Trypanosoma cruzi*

T. cruzi, the causative agent of Chagas' disease in humans, infects 16–20 million people in Central and South America and constitutes a prominent health problem. The parasite is a kinetoplastid protozoan whose life cycle alternates between an insect belonging to the family Reduviidae, and a mammalian host. Transmission is initiated by insect vectors which after a blood meal defecate and release infective metacyclic trypomastigotes near the bite wound. These infective stages differentiate from epimastigotes, the noninfective replicative form that live in the insect gut. Both forms are flagellated and highly motile. In contrast to the African trypanosomes, the vertebrate stages of *T. cruzi* are obligate intracellular pathogens and must enter host cells to replicate. After disruption of the membrane-bounded vacuole, parasites escape to the cytoplasm and differentiate into amastigotes, less motile with a very short flagellum and spherical body (Figure 1). After a 24 h lag period, amastigotes start dividing by binary fission, which occurs 7–10 times. After 5–7 days, more than 500 parasites have accumulated in the cytoplasm. When the replicative period is completed, amastigotes differentiate into trypomastigotes, the host cell ruptures and parasites are released into the bloodstream; thus, infection disseminates to other tissues. These released forms, equivalent to the metacyclic trypomastigotes, are called bloodstream trypomastigotes and are able to invade nearly every kind of nucleated cell (Figure 2). The *T. cruzi* life cycle (Figure 3) is completed when trypomastigotes are ingested by blood-sucking insect vectors. Amastigotes released from ruptured cells are also able to invade new host cells, probably involving different receptors from those used by trypomastigotes.

Invasion of the mammalian cell

Several antigens from the trypomastigote as well as host cell receptors are involved in sequential processes leading to invasion. The ability of *T. cruzi* to invade almost every nucleated cell from any mammalian species indicates the presence of ubiquitous and conserved receptor(s) on the host cell. Among

the parasite molecules involved in binding to the host cell, a relevant role has been attributed to trypomastigote stage-specific molecules of a large family that includes trans-sialidases/sialidases. Sialic acid on the surface of host cells influences the invasion process. *T. cruzi* parasites do not synthesize sialic acid, but make use of transialidases that transfer mammalian sialic acid to highly glycosylated mucin-like acceptors (35–50 kDa) on the parasite surface. Treatment with antibodies to both trans-sialidase or the mucin acceptors, desialylation of parasites or treatment with tunicamycin (which blocks glycosylation) inhibit infection, and mutants defective in sialic acid are more resistant to infection. Moreover, trans-sialidase released inside the phagolysosome desialylates lysosomal proteins, allowing activity of a parasite-encoded acidic pore-forming molecule (Tc-TOX or

Figure 1 Photomicrograph of *T. cruzi* amastigotes in the cytoplasm of mouse peritoneal macrophages (316 × magnification).

hemolysin) immunologically related to the C9 component of complement, and probably involved in escape into the cytosol. Penetrin, a 60 kDa trypomastigote-specific heparin-binding protein, has also been implicated in attachment to host cells. On the host surface, receptors binding fibronectin (as β_1 -integrins) and collagen play a role in the invasion process.

T. cruzi does not bind well to the host plasma cell membranes at 4°C, suggesting the need for energy-dependent mechanisms. In particular, those depending on parasite energy appear to play a key role in invasion. *T. cruzi* trypomastigotes invade the mammalian cell through a unique mechanism, distinct from phagocytosis, and without the need of pseudopodia formation and actin polymerization. Clusters of lysosomes gather in close proximity to the host plasma cell membrane at regions in contact with trypomastigotes. The parasite slides gradually into the host cell and fusion of lysosomes probably provides the membrane required for the formation of a vacuole that surrounds the parasite (Figure 4). Such an interaction is accompanied by, and probably depends on, alterations of cellular homeostasis, involving signal transduction events such as an increase in the intracellular concentration of free Ca^{2+} transients, both in the host cell and the infecting parasite. Ca^{2+} elevation in the cell is mediated by a parasite soluble factor that mediates its activity

through activation of host cell phospholipase C, at least in some cellular populations. Buffering or depleting intracellular Ca^{2+} results in inhibition of *T. cruzi* entry, indicating a physiologic role for such ions in the infection. *T. cruzi* invasion also directly activates the transforming growth factor β (TGF β) signaling pathway which is in turn required for parasite entry into the mammalian cells. Cruzipain, a cysteine protease from *T. cruzi*, is also thought to be involved in differentiation between amastigotes and trypomastigotes.

Immune responses of the host

Outcome of infection with *T. cruzi* in vivo

Following initial infection, the acute phase of Chagas' disease ensues. This phase is characterized by high blood parasitemia and extensive tissue parasitism. In a high proportion of Chagas' cases the acute phase is asymptomatic but, especially in children, fever, hepatosplenomegaly, adenopathy and myocarditis may occur. Parasitemia subsides after 1–2 months, coincident with the development of a specific immune response, and the patients enter a chronic stage of infection, without showing symptoms of disease. The asymptomatic phase of infection lasts for an unspecified period (up to 10–30 years), and is followed in 30–40% of cases by a clinical chronic disease, usually focused in the heart or the digestive tract. Chronic chagasic cardiac pathology may include arrhythmia, conduction abnormalities, apical aneurysm, myositis and infarction with fibroadipose replacement of the myocardium. In a final stage the most significant clinical manifestations of Chagas' cardiomyopathy include congestive heart failure, thromboembolic phenomena, severe arrhythmias and sudden death. Less frequent abnormalities in the digestive system involve hypertrophy of the esophagus or colon.

All mammalian species are susceptible to infection; however, the relative susceptibility of animals varies not only between, but also within, species. The genetic basis for this susceptibility is unclear. Genes both within and outside the major histocompatibility complex (MHC) loci have been implicated, as well as the genetic background of different strains of the parasite.

Immune response

Polyclonal activation and immunosuppression *T. cruzi* infection elicits both specific immune responses and several non-specific alterations in the homeostasis of the immune system in humans and experimental animals. The immune response is both humo-

ral and cell mediated and has been associated both with protection and pathogenesis.

A polyclonal activation of B cells (in particular Ly-1^+ [CD5]), and CD4^+ and CD8^+ T cells, follows early after infection with *T. cruzi*. The majority of the responding clones are not directed against parasite antigens. Although the parasite does not seem to possess any T cell-specific superantigens, an octapeptide from an 85 kDa parasite antigen has been shown to generate nonspecific B cell polyclonal activation. Elevated levels of type I interferons, interleukin 12 (IL-12) and IL-2, are found early after infection. These cytokines might be responsible for elevated cytolytic activity and secretion of interferon γ ($\text{IFN}\gamma$) by natural killer (NK) cells during early infection, and are probably involved in protection. An immunodepression stage characterizes the infection later during the acute phase. This immunosuppression is transient, although partially depressed responses have also been documented during the chronic stage of human and experimental infections. It is currently thought that the immunodepression undermines the defences against the establishment

and dissemination of the invading parasite in the host. During the acute stage of infection, T and B cells have an impaired ability to proliferate in response to mitogens as well as to specific or heterologous antigens. The unresponsive state has been associated with an impaired capacity to produce IL-2 and a downregulation of IL-2 receptor expression, and to an apoptotic death of CD4^+ T cells. Additionally, the activation of suppressor T cells, macrophages secreting nitric oxide (NO) or prostaglandin E and the downregulation of CD28 on T cells have all been proposed to explain the unresponsive state. Parasite molecules or soluble factors released by *T. cruzi* (proteins as well as a glycosylinositol phospholipid) mediate different features of the immunodepression *in vitro* and *in vivo* in a parasite dose-dependent way. *In vivo*, the immunodepression phase is also accompanied by an extensive thymic destruction and splenomegaly, whereas lymph nodes appear not to be affected to similar levels. High levels of $\text{IFN}\gamma$, released by $\text{CD4}^+\text{CD8}^-$ T cells, and specific antibodies are detectable during this phase, indicating the presence of active immune responses during

Figure 3 The life cycle of *T. cruzi*. (1) Metacyclic trypomastigotes are released in feces of the insect and enter the vertebrate host through the bite wound. (2) Trypomastigotes invade mammalian cells (see Figure 4). (3) After 30–120 min trypomastigotes escape from the vacuole and transform into replicative amastigotes. (4) Amastigotes multiply in the cytoplasm. (5) After a number of cycles amastigotes differentiate into trypomastigotes, which will rupture the host cell. (6) Amastigotes may also lyse infected cells before differentiation into trypomastigotes, and are thereby released into circulation, invade macrophages, survive, divide and further differentiate into trypomastigotes. (7) With a blood meal, the insect vector ingests bloodstream trypomastigotes, which in the insect midgut differentiate into noninfective and replicating epimastigotes. Epimastigotes further differentiate into metacyclic trypomastigotes in the hindgut of the vector, completing the life cycle.

Figure 4 *T. cruzi* invasion into a mammalian cell. (1) *T. cruzi* trypomastigotes attach to the cell surface. (2) Host cell lysosomes (○) migrate to the attachment site. (3) Lysosomes fuse with the plasma membrane at the attachment site and start to form an intracellular vacuole around the parasite. (4) The intracellular vacuole is formed. (5) Lysosomal glycoproteins are desialylated by the *T. cruzi* trans-sialidase and sialic acid (black dots) is transferred to parasite acceptors. *T. cruzi* Tc-TOX (■) anchors in the lysosome membrane. (6) The vacuolar membrane is disrupted. The parasite escape into the cytoplasm, where they will differentiate into amastigotes.

a stage of general dysregulation. In summary, the relevance of both polyclonal activation and immunodepression in the biology of the infection and outcome of disease is unknown. It is believed that the immunomodulation events occurring in the acute phase influence alterations later during the infection

by modifying the quality of the specific immune responses.

Protective immune responses The immune response controls the high parasite load in the acute phase to produce virtually undetectable parasitemia in the chronic phase. However, sterile immunity and complete parasite clearance and cure are unknown in humans and in experimental models of infection. Rather than achieving a cure, the immune response maintains a host-parasite balance which lasts for the lifetime of the infected individual.

NK cells, macrophages, B cells and both CD4⁺ and CD8⁺ T cells play important roles in resistance of mice infected with *T. cruzi*. Such diversity of cellular populations is reflected in manifold humoral and cellular immune effector mechanisms of destruction of both intracellular amastigotes and bloodstream trypomastigotes. Antibodies can lyse the parasite through activation of the classical or alternative pathways of complement. Antibodies might also lyse trypomastigotes through antibody-dependent cell-mediated cytotoxicity. Eosinophils, neutrophils, mononuclear cells and platelets have been shown to lyse the trypomastigotes when coated with specific antibodies. T cells can regulate production of such antibodies, lyse infected target cells or release cytokines (Table 1) that modulate different trypanocidal mechanisms of phagocytes. Whether they influence the physiology of infection in nonphagocytic cells is not known. Macrophage activation by tumor necrosis factor α (TNF α) IL-3, IFN α , IFN β , IFN γ or granulocyte-macrophage colony-stimulating factor (GM-CSF) leads to inhibition of the replication or killing of the intracellular forms of *T. cruzi*. Of these cytokines, IFN γ has been most closely associated with host resistance. Conversely, cytokines such as IL-4, IL-10 and TGF β counteract the effects of IFN γ during *T. cruzi* infection *in vitro* and *in vivo*. However, *T. cruzi* infection appears not to be a model for T_H1/T_H2 dichotomy, as in infection with *Leishmania major*. Cytokines belonging to both T_H1 and T_H2 are simultaneously produced during infection in a variety of mice, but the balance between cytokines belonging to either pattern appears to influence the outcome of infection. Such cytokine balance regulates the transcriptional rate and mRNA stability of inducible nitric oxide synthase (iNOS) by macrophages, mediating high output of NO. Macrophages produce reactive oxygen species (ROS) and NO and show induction of iNOS during the course of *T. cruzi* infection *in vivo*. Both NO and ROS are toxic for the parasite *in vitro*, and some trypanocidal drugs, such as nifurtimox or crystal violet, act by generating such species. In addition, the superoxide anion and

Table 1 Role of cytokines in the outcome of infection with *T. cruzi* *in vivo* and *in vitro*

Cytokine	Effect on <i>T. cruzi</i> infection
IFN γ	Reduces parasitemia and mortality. Activates trypanocidal activity of macrophages, mainly through induction of inducible NO synthase. The peak of production coincides with the high parasite load during the acute phase of infection
TNF α	Inhibits intracellular multiplication. Synergizes with and mediates IFN γ trypanocidal activity. It has been shown both to aggravate and protect <i>in vivo</i> . Produced by macrophages after <i>in vitro</i> infection with parasites
TGF β	Inhibits IFN γ -mediated trypanocidal activation of macrophages. Is involved in parasite penetration and intracellular multiplication. Increases susceptibility to infection <i>in vivo</i>
IL-1	Released by infected macrophages and endothelial cells. Probably associated with microcirculatory alterations, and thereby heart dysfunction
IL-2	Spontaneously released early after infection, its production is markedly suppressed during the acute phase of infection
IL-3	Activates a trypanostatic activity of macrophages
IL-4	Inhibits IFN γ -mediated macrophage activation and NO release. Its levels are increased in the chronic phase of infection, especially in susceptible hosts. Increases susceptibility to infection with at least some <i>T. cruzi</i> strains
IL-6	Decreases cumulative mortality <i>in vivo</i> . Released by endothelial cells after <i>in vitro</i> infection with <i>T. cruzi</i>
IL-10	Inhibits IFN γ -mediated macrophage activation. Increases susceptibility to infection. Increased in susceptible as compared with resistant strains of mammalian hosts
IL-12	Reduces parasitemia and mortality, through IFN γ - and possibly TNF α -mediated mechanism of resistance

NO might react with each other to form peroxynitrite, a stronger trypanocidal molecule than its precursors. Whereas the relevance of ROS is still controversial, NO is necessary for control of the parasite load both in *in vitro* activated macrophages and during *in vivo* infection with *T. cruzi*.

Pathogenesis and immunopathology Different mechanisms have been proposed to participate in the pathogenesis of chagasic cardiopathy, and probably all have some degree of involvement in such a process. Microvascular changes, as manifested by platelet aggregates, increased levels of P-selectin, thrombus formation and histochemical evidence of myocardial hypoxia in humans and experimental models, might cause focal necrosis. Conversely, the

reduction of parasympathetic ganglion cells in the heart and gut of chronic Chagas' patients has prompted suggestions for a role for denervation in pathogenesis. Vagal and myenteric plexus denervation could induce an increased sympathetic tone that may have a direct effect in heart arrhythmogenesis or gut megasyndrome. There is by now convincing evidence that immune responses are involved in pathogenesis. Chronic inflammatory reactions depend on a persistent antigenic stimulation by parasite antigens. Although a chronically infected host displays undetectable parasitemia and very rarely tissue amastigotes, parasite antigens have been detected in inflammatory infiltrates and such lesions correlate with the severity of the disease. Autoantibodies or autoreactive cellular responses generated through polyclonal activation or by parasite antigens cross-react with mammalian neurons, lymphoid cells, laminin, ribosomal proteins, sarcolemma, myocardial β receptors and myosin. The levels of some of these antibodies correlate with the clinical status (myosin for example), and some antibodies mediate physiologic alterations in the target cells. For example, parasite cross-reactive antibodies trigger neurotransmitter-receptor interactions in myocytes and thereby alter the physiology of normal myocardium. Tissue destruction by inflammatory cells is probably facilitated by the presence of parasite antigens and ectopic expression of adhesion molecules and histocompatibility antigens on the surface of infected or noninfected cells during infection. CD8⁺ T cells have been shown to dominate the inflammatory infiltrate; however, the pathogenic role for CD8⁺ T cells is not clear. In contrast, CD4⁺ cells from chronically infected mice comprise only 5–10% of the inflammatory infiltrate but have been shown to play a role in pathogenesis, as they are involved in the rejection of grafted syngeneic heart tissue. Hypothetically, almost every immunologic mechanism described as participating in protection might also be involved in tissue pathology. Whatever the damaging mechanism, no data presented as yet can explain the prolonged latent period between the initial infection and the pathologic changes 5–40 years later in human infection.

Escape mechanisms

As with all microorganisms, *T. cruzi* has developed stage-specific strategies to circumvent host defence mechanisms before, during and after entry into host cells. The major evasion method employed by *T. cruzi* is its promiscuity, in other words the ability to invade all nucleated cells, thereby hiding from the immune response. Although antigenic variation of

surface antigens has not been described in *T. cruzi*, many of the surface genes including those coding for enzymes necessary for invasion (trans-sialidase for example) are expressed as multigenic families. Expression of such antigens might be modulated by the parasite to present a constantly changing face to the host immune system. As an alternative escape mechanism, some of the components of these multigenic families do not possess enzymatic activity but have extensive cross-reactivities with their enzymatic relatives. Moreover, the active sites of such enzymes are not immunodominant, and are thereby protected from neutralizing immune responses. As a protective back-up, *T. cruzi* displays several molecules involved in invasion, but none of them appears to be an absolute requirement for invasion and inactivation of any of them rarely renders a complete inhibition. Soluble molecules shed or secreted by *T. cruzi* bind non-infected cells, and if correctly presented to the immune response they will divert it. Moreover, this phenomenon, and the presence of cross-reactive antigens, can convert a potent and sterilizing immune response into a detrimental one as it might also harm noninfected tissue. Once inside the lysosome Tc-TOX and trans-sialidase cooperate in *T. cruzi* liberation into the cytosol, thereby avoiding the toxic milieu in the phagolysosome. Extracellular trypomastigotes have also developed evasion mechanisms and are protected from activation of the alternative complement pathway by complement regulatory molecules displaying genetic and functional similarities to decay-accelerating factor (DAF).

Vaccines

Vaccination studies have been undertaken in a number of different animal species by using a variety of different antigens, including whole lysed parasites, subcellular fractions and purified/recombinant antigens. The results generally show that many of these antigen preparations reduce parasitemias during the

acute phase of the disease and convert lethal to non-lethal infections. However, no vaccination study has achieved complete protection and the vaccinated animals become infected. Reduction of parasitemia might reduce the incidence and severity of the chronic phase of the disease, and might constitute a goal for immunoprophylactic studies. In any case, alternative measures, such as eradication of the insect vector, control of the parasite in blood banks and chemotherapy of congenital and acute cases, have rendered considerable positive results in the battle against Chagas' disease during the last 10–20 years.

CHÉDIAK-HIGASHI SYNDROME

Charles M Perou and Jerry Kaplan, Division of Cell Biology and Immunology, Department of Pathology, University of Utah, Salt Lake City, Utah, USA

Chédiak-Higashi syndrome (CHS) is an autosomal recessive disorder of humans that results in the formation of 'giant' intracellular vesicles. The formation of these large vesicles results in impaired function, which often compromises cellular activities. Many of

the granule types affected in this disorder are required for proper immune cell function, and hence cause a severe immunodeficiency in afflicted individuals.

This rare human disorder has numerous pheno-

typically similar disorders in other species including beige mice, Aleutian minks, cats, cattle, and even killer whales. The beige mouse has been used as a model organism for the study of CHS for many decades, and much of what is known about CHS has been obtained through the study of these mice. Somatic cell fusion studies have suggested that beige mice, Aleutian minks and CHS patients have defects within homologous genes, therefore providing genetic evidence which supports the hypothesis that beige and CHS are genetically similar disorders.

CHS/beige primarily affects four classes of intracellular vesicles: lysosomes, melanosomes, platelet-dense granules and cytolytic granules (Figure 1). It is thought that the formation of these 'giant' vesicles is due to a malregulation of either vesicle fusion or fission. The net result of this single gene defect is a reduction in the number of vesicles and an increase in their average size. The mouse beige gene has recently been identified and will be discussed below.

The clinical phenotypes in CHS/beige are the formation of giant vesicles, pigment dilution, a bleeding tendency and a severe immunodeficiency. Giant lysosomes are found in almost every cell of the body. This defect causes impaired lysosome function, which is tolerated by many cell types but which may ultimately kill others (e.g. neurons). The formation of giant melanosomes causes a pigment dilution that results in a near albino appearance of most CHS patients. In these individuals, the hair, eyes, skin, or any combination of the three, are the sites of pigment alterations. In mice and other mammals this defect

results in an alteration in coat color. Platelet-dense granules also form anomalous large structures that result in a platelet storage pool deficiency. Due to this deficiency, CHS patients and beige mice have decreased platelet aggregation and a bleeding tendency.

It is within the immune system that the CHS/beige defect exerts its most profound and deadly effects. The cell types known to show the CHS defect of enlarged granules include CD8⁺ T cells, eosinophils, basophils, neutrophils, mast cells, macrophages, megakaryocytes, B cells and natural killer (NK) cells. Each of these cell types contains large lysosomes as well as enlarged specialized granules; for example, neutrophils often contain large granules derived from the fusion of azurophilic and specific granules. Neutrophils from affected individuals also show defective chemotaxis; they have normal bacterial phagocytosis but impaired intracellular killing of bacteria. It has been demonstrated for neutrophils and macrophages that the newly formed phagosomes often fail to fuse with lysosomes, thereby allowing the internalized bacteria to survive longer and to multiply.

A second cell type profoundly affected by the CHS/beige defect is the NK cell. The numbers of NK cells and their target specificity and binding appear normal, but these cells are unable to kill their targets. The beige mouse is often used as a NK cell-deficient animal in order to study the role of NK cells in various immune responses. It is believed that defective NK cell activity is due to impaired exocytosis of cytolytic granules. A very similar defect is also observed

Figure 1 Bone marrow macrophages from (A) a C57BL/6J mouse and (B) a C57BL/6J-bg/bg mouse (100 × magnification). Note the 'giant' lysosomes clustered near the nucleus in (B). (Reproduced with permission of Company of Biologists Ltd from Perou CM and Kaplan J (1993) Chédiak-Higashi-syndrome is not due to a defect in microtubule-based lysosome mobility. *Journal of Cell Science* 106: 99–107.)

in CD8⁺ T cells. The decreased activity of these cell types can be overcome *in vitro* by chronic stimulation with exogenously added cytokines and longer incubation times. Unfortunately, these results cannot be replicated *in vivo*. Other cell types of the immune system show the CHS defect (e.g. B cells, eosinophils, basophils and mast cells), but their function does not appear to be significantly compromised. For example, CHS patients and beige mice are capable of making antibodies against invading organisms.

Until the advent of antibiotics, infections killed most CHS patients. Today, the most deadly effect of the CHS mutation is the 'accelerated phase'. The accelerated phase is a mononuclear lymphoma-like cellular infiltrate that invades the major organs of the body. This infiltrate, along with the bleeding tendency, causes major organ failure, hemorrhage and the death of the afflicted individual. It is thought that the accelerated phase is triggered by a viral infection but the precise virus or even the cellular origin of this lymphoma, is not known.

The only cure for CHS is to prevent the accelerated phase. This can be done by whole body irradiation to kill the endogenous bone marrow that gives rise to the lymphoma, followed by allogeneic bone marrow transplantation. This treatment has worked in many cases, and has prevented the accelerated phase from recurring for up to 13 years in one patient. As these CHS patients age, however, other problems may arise, such as neurologic defects due to the loss of neurons. CHS is a candidate for gene replacement in hematopoietic stem cells, which would cure the immunodeficiency and prevent the accelerated phase, while also circumventing the problem of graft-versus-host disease.

The mouse beige gene has recently been identified using a Yeast Artificial Chromosome complementation approach. The human homolog of the beige gene was then isolated and shown to contain mutations within CHS patients. These data demonstrate that beige and CHS are due to mutations within orthologous genes. The Beige/CHS protein is approximately 3800 amino acids in length and contains a protein-protein interaction motif (WD40 repeats) and a highly conserved domain of unknown function. This conserved domain identifies homologs in *Saccharomyces cerevisiae* and *Caenorhabditis elegans*, demonstrating that this protein is conserved throughout evolution. The overall sequence of the

Beige/CHS protein is novel and gives few clues as to its biochemical function.

The salient feature in a number of inflammatory conditions, such as infection, hypersensitivity reactions or autoimmune diseases, is the presence of infiltrating leukocytes. The extravasating leukocytes are critical for host defense, leading to clearance of the inciting factors such as infectious agents and particulate antigens. However, it should be appreciated that leukocyte recruitment may also contribute to the pathogenesis of an underlying disease. The maintenance of leukocyte recruitment during inflammation requires communication between infiltrating leukocytes and the endothelium as well as various extravascular cells. These signals are mediated via the generation of early response cytokines, the expression of surface adhesion molecules and the production of chemotactic molecules. While many cytokines modulate cellular adhesion and promote leukocyte recruitment, few have been shown to directly affect integrin avidity. Recent studies have identified a superfamily of small, soluble, structurally-related cytokines called 'chemokines' (chemotactic cytokines) that appear to be excellent, physiologically relevant candidates for the rapid triggering of integrin-mediated adhesion and selectively induce the directional migration of various leukocyte subsets both *in vivo* and *in vitro* (Figure 1 and 2). These molecules and their receptors play critical roles in hematopoiesis, angiogenesis, cellular activation, cytotoxicity and wound healing, as well as in a variety of acute and chronic inflammatory disease states.

Characteristics of chemokines

Over 30 unique human and mouse cytokines have been identified as members of the chemokine superfamily (Table 1). Based on the presence or absence of an intervening amino acid residue located between the first two of the four conserved cysteine residues, the chemokine superfamily can be separated into two distinct subfamilies called the α (or C-X-C) and the β (or C-C) subfamilies. As the chemokines are secreted molecules, their cDNAs code for a precursor protein which contains a leader sequence (20–25 amino acids), which presumably enables the chemokines to

be produced, cleaved and secreted to yield a mature form at the cell membrane by a wide variety of cell types. Chemokines share many other similarities, including their high basic nature as well as their ability to bind heparin through heparin-binding domains. At the amino acid level these molecules exhibit between 24–80% homology. Chemokines in

Figure 1 Schematic model of leukocyte trafficking into inflammatory tissues. Many of the models describing leukocyte entry into inflammatory sites depend on at least three distinct molecular interactions: selectin-carbohydrate, chemokine-receptor, and integrin-CAM. As leukocytes circulate in the blood and lymph (1), they constantly survey the surrounding endothelial barrier for the presence of distress signals alerting them to problem areas. Once alerted, a sequential series of signals is required to mediate leukocyte entry into the extravascular tissues. With the release of distress mediators such as IL-1, TNF, LPS, or histamine, various selectin ligands are rapidly expressed and mobilized to the membrane of the activated endothelial cells within the tissue environment. The selectins mediate the initial tethering and rolling of responding leukocytes to the blood vessel wall slowing their transit through the circulation (2). Upon interacting with proadhesive signals (3), most likely provided by heparan proteoglycan- or extracellular matrix-bound chemokines, the integrin molecules on the leukocyte surface are altered from a conformationally inactive complex to a high avidity state permitting leukocyte binding to the expressed cell adhesion molecules (such as ICAM-1, VCAM-1, etc.) present on inflamed endothelial cell surface (3). At this point, leukocyte rolling stops and firm adhesion begins. These adherent leukocytes are then permitted to spread out along the activated endothelial barrier and migrate (with the assistance of various proteinases) through the vascular endothelial barrier and basement membrane into the extravascular tissue space (5). Once through, soluble as well as extracellular matrix- and heparan proteoglycan-bound chemokines derived from the inflammatory lesion form a concentration gradient promoting the directional migration of leukocytes from areas of low chemokine levels toward the areas of chemokine production.

their monomeric form range from 7 to 14 kDa and are active at concentrations ranging from 10^{-8} to 10^{-10} M. However, many of the chemokines form dimers, trimers and tetramers upon secretion. While chemokine dimer formation has been shown to be necessary for optimal ligand interaction with chemokine receptors by some investigators, this requirement is rather controversial as chemokine monomers have also been shown to be biologically active. Chemokine subfamily members are also coclustered on the same chromosomes. α Chemokines are clustered on human chromosome 4q12-q21, while β chemokines cluster on human chromosome 17q11-q21 and mouse chromosome 11. Lymphotactin (Ltn), a member of the 'C' subfamily (γ chemokines) lacking two of the typical four cysteine residues, is located on human chromosome 1. Many of the α chemokines possessing -ELR- residues at position 4-6 near the N-terminus have been shown to be potent mediators of neutrophil chemotaxis both *in vitro* and *in vivo* and have the capacity to bind the shared interleukin 8 (IL-8) receptor type II. All α chemokines which lack the -ELR- motif fail to chemoattract neutrophils or bind the shared IL-8 type II receptor. Chemokines are not typically expressed in

unstimulated cells, tissues or cell lines but are rapidly induced (usually within 1–2 h post stimulation) in response to either endogenous or exogenous stimuli. Typically, agents which enhance inflammation (e.g. lipopolysaccharide (LPS), IL-1, tumor necrosis factor α (TNF α), injurious stimuli and infectious agents) or immune activation (e.g. lectins, antigenic stimulation, mitogens, immunoglobulin E (IgE) antigen and phorbol esters) also promote chemokine production. Chemokine mRNA can comprise up to 1% of the total mRNA content of a stimulated cell. Chemokine production appears to be ubiquitous, in that almost every cell and tissue type in the body has been shown to produce chemokines upon stimulation. It is believed that chemokines produced within a given tissue, rather than remaining in solution, are preferentially immobilized through low-affinity binding to heparin-bearing proteoglycans (HP) on the vascular endothelial cell barrier or to extracellular matrix proteins within the extravascular tissues (Figure 1 and 2). As chemokines possess GAG-binding sites and bind heparin through their carboxyl-termini, this binding may be important in cytokine localization and immobilization on endothelial cells and matrix proteins as well as their biological activity.

Biological activities

The chemokine subfamilies can be distinguished from one another by their apparent leukocyte specificity in mediating cell migration and adhesion. Typically, ELR⁺ α chemokines induce neutrophil but not

Figure 2 Leukocyte entry and migration within an inflammatory environment. Once across the vascular barrier, leukocytes directionally adhere and migrate along the various extracellular matrix proteins and CAMs within the tissue toward the sites of chemokine production (1). The chemotactic gradients are believed to be maintained via chemokine binding to extracellular matrix proteins (e.g. fibronectin (FN), collagen (CN), etc.) and heparan proteoglycans (HP) found within the tissues (2). The migrating leukocytes directionally move from regions of low levels of chemoattractants to regions containing higher concentrations. As leukocytes infiltrate sites of increased chemokine concentrations, chemokine receptor desensitization may inhibit further migration in response to a given chemokine gradient. In addition, it seems quite possible that the expression of various matrix- and proteoglycan-degrading enzymes may also serve to regulate leukocyte entry and departure from inflammatory sites by the cleavage of chemokine presenting molecules. The presentation of a chemokine to a specific cell surface chemokine receptor (CXCR or CCR) induces a complex series of intracellular signals that facilitate cell adhesion and migration (3, 4). As chemokine receptors are associated with a heterotrimeric G protein complex (with each receptor possessing its own unique G protein profile), signaling through these molecules is believed to transduce a signal(s) necessary to activate integrin adhesiveness (5). Both chemokine receptors and integrin molecules mobilize to the leading edge of the migrating leukocyte, optimizing ligand recognition and promoting directional migration. Signals induced by these receptors also induce an increase in integrin expression and the release of various metalloproteases/TIMPs may assist in transverseing the various layers of the basement membrane and tissue environment. Furthermore, it seems most likely that only certain integrin molecules are activated by chemokine receptor interactions (depending on the receptor and its G-protein association) possibly by regulating leukocyte adhesion to specific extracellular matrix proteins (5). A greater definition of the interplay between chemokines, adhesion molecules, and enzyme release may further elucidate the true mechanisms required for leukocyte transmigration through the vascular barrier and basement membrane.

monocyte migration, while β chemokines predominantly act on monocytes and macrophages with no activity on neutrophils. Besides neutrophils and monocytes, both α and β family members are active on a number of cell types (Table 2). In addition to the subtype of leukocyte being examined, the chemokine responsiveness of a cell may depend on its activation state. In addition, stimulation of certain cell populations with cytokines or activation stimuli appears to enhance their chemokine responsiveness. Chemokine activities are not only restricted to chemotaxis and adhesion, multiple other proinflammatory effects have been described. These include the induction of superoxide anion, nitric oxide, metalloproteinases, intracellular granules and cell adhesion molecules (Table 2). Many of these biological properties are believed to contribute not only to their immunological roles in inflammation but also to their physiological roles in tissue repair and cellular growth/differentiation.

Chemokine receptors

Chemokine receptors are members of the rhodopsin or serpentine receptor superfamily and have the characteristic G protein-coupled seven hydrophobic transmembrane spanning regions. These receptors also exhibit varying degrees of homology, particularly within their transmembrane spanning regions. Studies have revealed a number of human chemokine receptors with various chemokine binding characteristics (Table 3). Chemokine ligand-receptor interactions initiate a characteristic pattern of responses, including shape change, integrin activation, chemotaxis, degranulation, enzyme secretion and respiratory burst. Depending on the chemokine and leukocyte subtype, receptor ligation has been shown to activate a number of signaling pathways, including phosphoinositol hydrolysis, arachidonic acid metabolism, the activation of various kinases, and the rapid elevation of diacylglycerol and cytosolic Ca²⁺ levels. In addition, all chemokine receptors contain one or more of the consensus sequences for G_i protein activation which is believed to be essential for the high-affinity binding of chemokines and their adhesion/migration activities.

Pathological disease states

Many chemokines have been shown to be present in numerous inflammatory and noninflammatory disease states, including sepsis, atherosclerosis, arthritis, cystic fibrosis and asthma. In many of the inflamed lesions the presence of chemokines is highly correlated with the level of leukocyte infiltration within

Table 2 *In vitro* effects of α and β chemokine family members

Chemokine	Target cell	Biological effects on various target cells
<i>α Chemokines</i>		
IL-8, GRO α , GRO β , GRO γ , NAP-2	Neutrophils	Chemotaxis; shape change; increased degranulation; increased respiratory burst; increased cytosolic Ca ²⁺ ; increased adhesion to endothelial cells, fibrinogen and extracellular matrix proteins; increased <i>Candida albicans</i> growth inhibition; increased expression of CD11a, CD11b, CD11c and CD18; increased lysosomal enzyme release; decreased L-selectin expression
PF-4	Neutrophils	Chemotaxis; superoxide release
IL-8, GRO α	T cells	Chemotaxis; stimulated polyphosphoinositide hydrolysis
IP-10	T cells	Chemotaxis; increased adhesion to endothelial cells and extracellular matrix proteins
IL-8	B cells	Inhibits IL-4-induced IgE production; inhibits B cell proliferation
IP-10, IL-8	NK cells	Chemotaxis; increased killing of tumor targets
IP-10	Monocytes	Chemotaxis
IL-8	Basophils	Chemotaxis; inhibits histamine release; increased leukotriene release
IL-8, IP-10	Keratinocytes	Increased proliferation
IL-8	Endothelial cells	Increased blood vessel proliferation (angiogenic)
PF-4	Endothelial cells	Increased ICAM-1 expression; decreased blood vessel proliferation (angiostatic)
IL-8, GRO α	Melanomas	Increased adhesiveness and haptotactic response
IL-8	Smooth muscle	Chemotaxis
PF-4, CTAP-III, β -TG, NAP-2	Fibroblasts	Chemotaxis; increased proliferation
<i>β Chemokines</i>		
MCP-1, MCP-2, MCP-3, MIP-1 α , MIP-1 β , RANTES, C10	Monocytes	Chemotaxis; increased superoxide anion release; increased cytosolic Ca ²⁺ ; increased adhesion to endothelial cells and extracellular matrix proteins; increased <i>N</i> -acetyl- β -glucuronaminidase; increased cytostatic augmenting activity; increased intracellular calcium; induced arachidonic acid release
MCP-1, MIP-1 α , MIP-1 β , RANTES, MCP-3, C10	T cells	Chemotaxis; increased adhesion to extracellular matrix proteins and cytokine-activated endothelial cell monolayers; increased metalloprotease and TIMP release; increased CTL killing of tumor cell targets; degranulation; costimulation
MCP-1, MIP-1 α , RANTES	Mast cells	Chemotaxis; histamine release
MCP-1, MCP-3, MIP-1 α , RANTES	Basophils	Chemotaxis; increased histamine release; increased intracellular calcium; increased leukotriene release; increased adhesion
MIP-1 α , MCP-1, RANTES, MCP-3	B cells	Chemotaxis; increased proliferation; increased IgE and IgG4 production
MIP-1 α , MIP-1 β , RANTES, MCP-1	NK cells	Chemotaxis; increased killing of tumor targets; increased adhesion to extracellular matrix proteins
MIP-1 α , RANTES, eotaxin, MCP-3	Eosinophils	Chemotaxis; induces cationic protein release; increased intracellular calcium; increased cell surface integrins
MIP-1 α , MCP-3	Neutrophils	Weak increases in intracellular calcium; increased shape change

CTL, cytotoxic T lymphocyte; ICAM, intercellular cell adhesion molecule; NK, natural killer; TIMP, tissue inhibitor of metalloproteinase.

the diseased tissue. Under some conditions the chemokines facilitate leukocyte adhesion and transmigration into compromised tissues, resulting in the phagocytosis and killing of microbes or allogeneic cells (host resistance), while in other states aberrant chemokine production contributes to the induction and progression of disease pathology (Figure 1 and 2). Several chemokine receptors act as human immunodeficiency virus 1 (HIV-1) coreceptors. T cell tropism is associated with CXCR4 expression whereas macrophage-tropic strains bind to CCR5. A

greater understanding of the complexities of the chemokines that mediate cell adhesion and transmigration may assist in the orchestration, regulation and control of various pathological disease states.

CHEMOTAXIS

Peter C Wilkinson, Department of Immunology, University of Glasgow, Glasgow, UK

Chemotaxis, the directional locomotion of cells towards a source of a chemical gradient, was first described in bracken fern spermatozoa by Pfeffer in 1884. Shortly afterwards (1888) Leber described a similar phenomenon in mammalian leukocytes responding to a focus of injury. Since then, chemotaxis has been accepted as an important mechanism for mobilizing phagocytic and immune cells at sites of infection, tissue injury, and immune reactions. However, it is only recently that something has been learnt about the sensory mechanisms by which cells detect attractants and about the motor which provides the power for their locomotion, and knowledge of both is still very incomplete. Chemotaxis is simply a special form of locomotion, and a brief preliminary description of leukocyte locomotor behavior will help understand its mechanism.

Morphological events of leukocyte locomotion

Leukocytes which are unstimulated are spherical and immotile. This is their morphology both in the bloodstream and after careful *in vitro* preparation. Following stimulation with a chemoattractant, the cells change shape within a minute or so by extending a pseudopod, or lamellipodium, at one pole. Slow contraction waves may then pass antero-posteriorly down the cell from this point. The cell thus adopts a typical, tapered, locomotor morphology (Figure 1). The ruffled anterior lamellipodium is initially hyaline and is rich in actin and actin-associated proteins but lacking in organelles. Behind it is the organelle-rich cell body with a posterior tail (uropod) which forms after the complete passage of a contraction from front to back. All these changes occur whether the cell is in suspension or on a surface. Surfaces, either two-dimensional or three-

Figure 1 A neutrophil migrating on a surface. Note the broad, ruffled anterior lamellipodium which is free of organelles. Behind this is the cell body containing the nucleus and cytoplasmic organelles. The cell is 'waisted' about a third of the way down. Observation of moving cells shows that this is due to a constriction which passes from front to back as the cell moves forward. A posterior tail is also seen. Special techniques reveal that the anterior lamellipodium is rich in actin and actin-associated protein and that cell surface receptors are frequently concentrated at this pole (not shown in this picture). (Photography by courtesy of Dr Wendy Haston).

dimensional (such as collagen or fibrin gels) give purchase for locomotion. Similar changes are seen in neutrophils, macrophages, lymphocytes and eosinophils. They are initiated by binding of 'chemotactic' factors to cell surface receptors, and all of these cells show chemotaxis, though the neutrophil is the best studied. The term chemotactic factor is imprecise since such factors also activate chemokinesis (below) and other functions such as adhesion, oxidative metabolism, secretion, etc.

Definitions of locomotor reactions

Random and directional locomotion

The paths of moving cells may be directional or random. In random locomotion, the different cells of a population move in directions that are random in relation to one another and to the environment, but the individual cells may persist in their initial direction of locomotion for several minutes. This is called a 'persistent random walk'. When observed over long periods, the cells turn so that, over long periods (>5 min), mean square displacement is proportional to time. In directional locomotion the cells show preference for a particular direction, and their morphological axis is oriented in that direction.

Locomotor responses to physical or chemical cues

The environment of the cell may determine both directional and random locomotion. Chemical cues determine reactions as follows.

Chemokinesis Chemokinesis has two forms: orthokinesis and klinokinesis. In orthokinesis, the speed or frequency of locomotion is determined by the magnitude of the stimulus, i.e. the attractant concentration.

In klinokinesis the amount of turning the cell does is determined by the magnitude of the stimulus. Orthokinesis is thus a straightforward acceleration or deceleration of cells in response to stimuli. It is certainly important in leukocytes. Klinokinesis is of uncertain importance in leukocytes, though, in bacteria such as *Escherichia coli*, chemicals determine whether the organisms 'tumble' or show straight runs. In the rest of this article, the term 'chemokinesis' will be used synonymously with 'orthokinesis' as defined above.

Chemotaxis Chemotaxis is a reaction by which the direction of locomotion is determined by the direction and magnitude of a chemical stimulus. The stimulus is usually in the form of a concentration gradient. In leukocytes, chemotaxis is always positive, i.e. towards a gradient source. Negative chemotaxis away from a source may exist in other organisms.

Contact guidance Chemotaxis is not the only cue that causes cells to move directionally. Contact guidance is a reaction by which the direction of locomotion is determined by the shape or curvature of the substratum on which the cell moves, i.e. by physical rather than chemical properties of the environment. For example, in aligned matrices of collagen or fibrin, neutrophils and lymphocytes prefer to move in the axis of the aligned fibers rather than across them. Cells are equally free to move in both directions in that axis, i.e. this is not a unidirectional locomotion, like chemotaxis. It is likely to be an important determinant of the ability of leukocytes to accumulate, particularly in tissues with complex patterning.

Locomotor capacity Leukocytes only show the capacity for locomotion at certain stages of their

development. Thus myeloid precursors in bone marrow are nonmotile, and lack chemotaxis receptors, but they acquire these as they develop, so that virtually all blood neutrophils and monocytes have a capacity for locomotion and chemotaxis. T lymphocyte precursors may be attracted chemotactically into the thymus, though as they mature, they may lose locomotor capacity. Many lymphocytes in blood and peripheral lymphoid tissues are not motile in the G_0 stage of growth, but develop locomotor capacity when they enter the G_1 phase of cell cycle if cultured in the presence of mitogen or antigen. Obviously locomotor capacity is an essential prerequisite for chemotaxis, chemokinesis, etc.

Haptotaxis The term haptotaxis was introduced by Carter in 1967 to describe directional locomotion on a surface bearing a gradient of changing adhesiveness. It is now used in a different sense to describe chemotaxis on gradients of surface-bound attractants. This is postulated to be important for transmigration of leukocytes across vascular endothelium and through connective tissue matrices towards sites of inflammation. Leukocyte migration requires contact with a surface but is not always dependent on adhesion since all the morphological changes described above occur when chemoattractants are added to cells in suspension. Moreover cells are capable of migrating through three-dimensional matrices without adhering since they can gain purchase by using the meshwork of fibres like a climbing frame. Nevertheless on two-dimensional surfaces, migration must be dependent on adhesion and there is now much evidence that, in sites of inflammation, the adhesion of both leukocytes and vascular endothelial cells is greatly increased.

How do leukocytes perceive chemotactic gradients?

Various explanations have been proposed for how a cell exposed to a gradient knows that the concentration on one side is higher than on the other and how it translates this information into locomotion in the direction of the highest concentration. Leukocytes can detect differences of as little as 1% in concentration across their lengths. Various ideas are as follows.

Spatial detection of a gradient

Stationary leukocytes exposed to a gradient put out a pseudopod in the direction of the gradient source before the cell has moved, possibly because receptor occupancy by ligand on the side facing the gradient source is higher than receptor occupancy on the other side. The cell response occurs where receptor

occupancy is highest. There are difficulties with this idea. The difference in receptor occupancy between the two sides may be very small and there is no easily imagined biochemical mechanism for the cell to perform the complex computations involved in spatial sensing and converting them into a polarized response.

Temporal detection of a gradient

Bacteria are small and fast-moving and it is believed that they move from point to point, sample the attractant concentration as they move, and act on the information thus received. Thus they detect the gradient in time. This requires a simple memory, the biochemistry of which is simpler than for spatial sensing. However, leukocytes detect gradients without moving. It has therefore been suggested that temporal sensing is determined not by movement of the cell but by movement of receptors on the cell surface. Receptors moving forward on the front of the cell experience increased ligand binding, which would determine increased cytoskeletal activity and motion at this region. At the cell's rear the opposite would be the case.

Chemotaxis may be a stochastic process

Neither spatial nor temporal mechanisms explain why leukocytes assume a front-tail polarity (Figure 1) in uniform concentrations of attractant. Under these conditions the cells ought to respond uniformly all over if the response resulted from a simple ligand-receptor interaction linked to the cytoskeleton. One possibility is that the cellular response is determined by the position on the cell surface at which the first signal is received. This requires the attractant concentration to be low enough to allow a cell to distinguish a first signal from subsequent signals. At low attractant concentrations, cells appear to be able to do this, but at higher concentrations, they show irregular morphologies when stimulated and take a few minutes to adopt a head-tail polarity. Possibly one pole becomes dominant due to chance fluctuations in receptor occupancy or signal transduction in different parts of the cell. In gradients, most cells will polarize up-gradient because most cells will receive their first signals on the side facing the gradient source. Both in gradients and in uniform concentrations, polarization is stabilized by redistribution of receptors to the head of the cell so that subsequent ligand-receptor interactions are most likely to occur there. If the stochastic model is correct, the molecular mechanisms for chemotaxis and chemokinesis are identical, and the path of locomotion of the cell, random or directional, is determined by the topographical distribution of attractant molecules rather than

Table 1 Chemokine attractants for leukocytes

by different cellular mechanisms for locomotion in gradients or in isotropic attractant concentrations.

Chemotactic factors

The term chemotactic factor is used of molecules which stimulate the directional locomotion of cells in gradients. In many cases a formal demonstration of directional locomotion has not been made and the less specific term chemoattractant is often used instead. There is a vast literature documenting such activity of many molecules for different classes of leukocyte. Recent interest has centered on the chemokine family of cytokines, different members of which are specific attractants for particular leukocytes, and which are believed to play a central role in inflammation. It is not possible to discuss all of these here but Table 1 lists some of the important chemokines and Table 2 lists some of the better-known nonchemokine attractants. Chemokines bind to serpentine seven membrane-spanning domain

receptors of the rhodopsin superfamily (type III transmembrane proteins) which are linked to trimeric GTP-binding proteins of the $G\alpha_1$ class. Many of the nonchemokine attractants bind to receptors of this family as well, e.g. formyl peptides, C5a, but other attractants, e.g. interleukin 2 (IL-2), IL-15, transforming growth factor β (TGF β), tumor necrosis factor α (TNF α), stimulate chemotaxis through other types of receptor, so no generalizations can be made about the structure of chemotaxis receptors. The responsiveness of lymphocytes to chemoattractants is more complex than these tables would suggest, since there are many classes of lymphocyte, and, for example, neither B cells nor natural killer (NK) cells are included in the tables although there is literature describing attractants for both.

Importance of chemotaxis and chemokinesis *in vivo*

These reactions have been defined in *in vitro* studies,

and are difficult to study with precision *in vivo*. Buckley, in 1963, made small burns in tissues with a microelectrode and observed leukocytes migrating directionally to the injured site. This is similar to the reaction of 'necrotaxis' described by Bessis in which individual red cells are damaged with a laser, and in which nearby neutrophils migrate in and ingest the damaged red cell, but only immediately after the burn. Chemotactic gradients *in vivo* may be easily disturbed. However, if chemotactic factors are also all chemokinetic factors, it is possible that leukocytes leaving a vessel will move around at speed even in the absence of a gradient. Those that get closest to the lesion, where gradients are likely to be sharpest, will then pick up the gradient and move directionally to the lesion site.

Methods

There are two basically different types of assay in use to study chemotaxis. The first is to film, with a camera or videotape, the detailed movements of cells and to measure speed, direction, etc. in different absolute concentrations and different concentration gradients of attractant. This gives precise information about the reactions defined above, but requires fairly specialized equipment. The second is to measure the distribution of a cell population at a fixed time-point after exposure to an attractant in uniform concentration, gradients, etc. This is the basis of the widely used filter assays, agarose assays, etc. and the methodology and measurement are simple. However, these assays only give indirect measures of the reactions defined above and it is difficult to dis-

tinguish chemotaxis from chemokinesis using them. This has resulted in much confusion, and, for example, many workers equate directional locomotion with chemotaxis, and random locomotion with chemokinesis. These are not synonymous as the definitions above make clear.

CHEMOTAXIS OF LYMPHOCYTES

Peter C Wilkinson, Department of Immunology, University of Glasgow (Western Infirmary), Glasgow, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Lymphocytes have long been known to be motile cells, but study of their locomotion has lagged behind that of monocytes and neutrophils, partly because of the heterogeneity of lymphocytes and their migratory behavior. Under normal circumstances there is continuous recirculation of both T and B cells between the blood and the lymphoid tissues. The recirculating population consists of naive small lymphocytes which are not in cell cycle. When lymphocytes recognize antigen, their migratory behavior alters. These cells enter the cell cycle and leave the recirculatory pool. Their adhesion phenotype changes, since they lose L-selectin and lose their affinity for the high endothelial venule (HEV) cells of lymphoid tissue. At the same time, they show increased expression and activity of many other adhesion molecules which allow them to attach to inflammatory endothelia, to cluster round antigen-presenting cells, and to bind to target cells for cytotoxicity. Thus the lymphocyte changes from a cell monitoring the environment for antigen to a cell that is focused on to effector functions. As would be expected, there are changes in locomotor properties between resting and activated lymphocytes which reflect these changes in function.

Small recirculating lymphocytes

Most of the lymphocytes in blood are recirculating cells. These cells give poor responses to most cytokines which have been reported to be lymphocyte chemotactic factors. It is difficult to induce more than 5–10% of blood lymphocytes to respond to any of these agents. However, small lymphocytes show a rapid change from a spherical to a polarized shape on contact with cultured HEV cell monolayers. Many of the cells transmigrate rapidly across to the undersurface of the monolayer where they continue to show active locomotion. It is likely that locomotion is activated by contact between specific surface molecules on the lymphocyte and the HEV. The chemokine, stromal cell-derived factor 1 (SDF-1) has recently been shown to attract resting T cells and is therefore likely to be a signal for lymphocyte recirculation.

Locomotion and chemotaxis of T cells: the role of activation

The capacity of lymphocytes from blood or lymphoid tissues to respond to chemoattractants is considerably enhanced by a period of 12–48 h of culture in the presence of activating agents. Polyclonal activators such as CD3-specific antibody, phytohemagglutinin (PHA), concanavalin A (con A), or even fetal calf serum will increase the proportion of locomotor cells from 10% to 30–70%. Antigens such as purified protein derivative of *Mycobacterium tuberculosis* (PPD) or superantigens such as staphylococcal enterotoxin B (SEB) have a similar effect. These are not direct chemoattractant effects. If the cultured cells are washed and resuspended in the presence of a fresh preparation of the activator, they may show no response, but if they are resuspended in their own supernatant medium, they do respond, suggesting that chemotactic cytokines are released during culture. Both lymphocyte activation and the release of attractants into the supernatant are dependent on the presence of accessory cells and highly purified T cells fail to become activated.

Following culture in the presence of accessory cells, the activated T lymphocytes can be purified and will then show chemotactic responses to pure cytokines (see tables 1 and 2 of the 'Chemotaxis' article). Interleukin 2 (IL-2) and IL-15 are both good chemotactic factors for these cells. The shared β chain (and probably also the γ chain) of the IL-2 and the IL-15 receptor are essential for this activity. The chemotactic activity of IL-15 probably plays a major role in recruitment of T cells into the lesions of rheumatoid arthritis. IL-16 also is a T cell attractant with a selective activity for CD4⁺ cells. Several chemokines also have activity. They include the α (C-X-C) chemokines, IL-8, and IP-10 (induced by IFN γ), and the β (C-C) chemokines, MIP-1 α and β , MCP-1, -2, -3 and -4, and RANTES. During activation with PPD, SEB or anti-CD3, as detailed above, sufficiently large quantities of IL-8 are released by monocytes to stimulate locomotion of T lymphocytes. β Chemokines have very little activity for T lymphocytes cultured for 24–48 h with the above-mentioned activators, but, during a week of culture with IL-2, the lymphocytes acquire chemokine receptors and show stronger locomotor responses to MIP-1 α and RANTES. The list of presently known attractant

cytokines is certainly incomplete. The profusion of lymphocyte attractant factors suggests that each may have specific roles in different types of lesion, but this is conjecture at present.

B cells

B cells, like T cells, recirculate and their first encounter with antigen may be in the T cell zone of lymphoid tissue where they meet antigen in clusters with interdigitating cells and T cells. Antigen-reactive B cells then migrate to the follicles to form a germinal center where a second encounter with antigen, in the form of immune complexes on the surfaces of follicular dendritic cells (FDCs), takes place. Further development to antibody-forming or memory cells also requires contact with CD40 ligand (CD40L)-positive germinal center T cells. All of these processes require active locomotion by B cells. Like T cells, B cells respond much better to attractants once they are activated.

Resting (G_0) B cells acquire locomotor activity during culture *in vitro* with T cell products, IL-4 and anti-CD40 (which mimics CD40L), and the motile cells are in the G_1 phase of growth. After a few hours of culture with these factors, the B cells are capable of locomotor and chemotactic responses to anti-immunoglobulin (anti-IgM and anti-IgD). Germinal center B cells die rapidly in culture unless they receive rescue signals, and anti-CD40 provides such a signal. Germinal center cells not only survive but become motile in culture in anti-CD40+IL-4. These cells, again, are attracted by anti-immunoglobulin and, since they have switched isotypes, they are capable of recognizing anti-IgA and anti-IgG as locomotor signals. This suggests that antigen may be a natural chemoattractant for B cells. It is possible, but has not been investigated, that germinal center cells migrate in antigen gradients towards FDCs. Immune complexes activate complement and it has been reported that germinal center B cells cultured with FDCs respond to C5a as a chemotactic factor. This could also form a gradient which would bring B cells into contact with FDCs.

Natural killer (NK) cells

There is little information on NK cell locomotion, though time-lapse films of these cells attached to target cells show vigorous locomotion of the attached cytotoxic cells, which then become released once the target cell dies. Reports suggest that NK cells,

especially after activation with IL-2, can respond to chemoattractants including the chemokines MIP-1 α , MCP-1, RANTES and IL-8, as well as IL-2 itself and C5a.

CHEMOTAXIS OF MACROPHAGES AND MONOCYTES

Peter C Wilkinson, Department of Immunology, University of Glasgow (Western Infirmary), Glasgow, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The locomotor behavior of monocytes and macrophages, and their behavior in response to attractants, are as described in the article 'Chemotaxis'. Like neutrophils, they show chemotactic and chemokinetic responses under appropriate conditions and the direction of their locomotion also shows guidance in relation to aligned fibrous matrices. Monocytes and macrophages are quite strongly adherent cells and spread rapidly on substrata *in vitro*. As a consequence, their rate of locomotion on such substrata is slower than that of neutrophils, but is faster than that of fibroblasts which are even more adherent.

Locomotor capacity and macrophage heterogeneity

The locomotor capacity of mononuclear phagocytes is determined by their differentiation status. Marrow precursor cells (as those for neutrophils) are non-motile and motility is acquired as these cells develop into monocytes. This is illustrated by the behavior of monoblast lines such as U937 which develop locomotor capacity only on addition of agents such as dibutyryl cyclic AMP or cytokines which drive differentiation into monocyte morphology. These differentiated monocytes are polarized, motile, and have chemotactic receptors not found on their unstimulated precursors. Most blood monocytes are also motile and respond to a range of attractants (see below). Once monocytes leave the blood and become macrophages, they may differentiate into many forms depending on the nature and site of stimulation, and these heterogeneous macrophages vary widely in locomotor activity. This can be studied well using peritoneal exudate macrophages, e.g. from mice. Following an inflammatory stimulus such as thioglycollate, many highly motile macrophages enter the peritoneum, newly recruited from blood monocytes. However, following an immunological stimulus such as *Corynebacterium parvum* or BCG, a more mixed exudate is found with many lymphocytes as well as macrophages. These macrophages also are motile, but less so than those found in thioglycollate exudates. In immunologically stimulated exudates, the lymphocytes are very motile, and these activated lymphocytes show chemotactic responses.

Locomotion and chemotaxis contribute to inter-

actions between macrophages and lymphocytes (see below). Macrophages in culture may slowly lose their motile behavior, especially when they become adherent and sessile and resident peritoneal macrophages usually show little locomotor behavior and respond poorly to attractants. A similar state of affairs may exist in the pulmonary alveoli in which cells newly recruited in response to inflammation are more motile than the resident macrophage population. Macrophages in other tissues may form tight adhesions with neighboring tissue cells. Presumably, macrophages such as hepatic Kupffer cells have little requirement for locomotor activity, since agents needing removal are brought to them by blood flow, though this is difficult to study since methods for isolation may damage surface receptors on such cells.

Chemotactic responses

Like neutrophils, monocytes and macrophages show accurate chemotactic responses to microorganisms, and respond to factors such as formyl-Met-Leu-Phe, C5a, C5a des Arg, leukotriene B₄, platelet-activating factor, thrombin and denatured proteins or breakdown products of proteins such as elastin, and these responses are probably important both for the microbicidal role and the scavenger role of macrophages. In the latter role, alveolar macrophages are reported to be attracted to, and to ingest, surfactant lipoprotein, presumably in degraded form.

These factors are not monocyte or macrophage specific and may attract neutrophils or other leukocytes strongly. Monocytes also respond to many of the C-C (β) chemokines. These chemokines (MIP-1α and β, MCP-1, -2, -3 and -4, and RANTES) attract blood monocytes but not neutrophils. This allows selective attraction of monocytes into lesions containing these molecules, though the attraction is not completely specific, since the same chemokines may also attract T lymphocytes or eosinophils (see Table 1 of 'Chemotaxis' article). Cell specificity is determined by the possession by different cells of receptors for β chemokines (CCR1-8). Of these receptors CCR1 (which binds MIP-1α, MCP-3, MCP-4 and RANTES) is the most strongly represented on human monocytes. Other cytokines that attract mononuclear phagocytes are transforming growth factor β

(TGF β), granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), tumor necrosis factor α (TNF α) and lymphotoxin (TNF β).

Attraction of other leukocytes by products of macrophages

Macrophages are important generators of attractants for other cell types and there is an extensive literature describing such factors. For example, many of the chemokines are made and secreted by monocytes or macrophages. These include neutrophil attractants such as interleukin 8 (IL-8). IL-15 is a molecule with functions similar to IL-2 but made by macrophages (and other cells) rather than by T cells. It is an effective attractant for T lymphocytes and is found in large amounts in the lesions of rheumatoid arthritis together with several of the chemokines. Murine macrophages from *C. parvum*-stimulated peritoneal exudates do not attract nearby lymphocytes unless they are given a phagocytic stimulus. However, immediately after phagocytosis, the macrophages release a brief pulse of an as yet unidentified attractant which causes nearby lymphocytes to migrate in by chemotaxis and to cluster round the macrophage. This may be a mechanism for focusing lymphocytes round a macrophage that is presenting newly processed antigen.

Clinical abnormalities

The most interesting of these is probably the observation that both patients with certain tumors (melanoma, certain carcinomas) and tumor-bearing experimental animals may have monocytes or macrophages which migrate poorly in chemotaxis assays. This is due to an inhibitor released by tumor cells and is reversed by removal of the tumor.

CHEMOTAXIS OF NEUTROPHILS

Peter C Wilkinson, Department of Immunology, University of Glasgow, Glasgow, UK

Neutrophil locomotion in inflammation

Neutrophils, the most numerous of the white blood cells, are the classical cells of acute inflammation and appear at inflammatory sites within a few hours of tissue injury. This mobilization from the bloodstream requires two events, each with its own molecular recognition mechanisms, the first being adhesion to vascular endothelium at the inflamed site, and the second, migration from the vessels in response to signals generated in the damaged tissue. These events occur in concert. In sites of inflammation, vascular endothelial cells rapidly become more adhesive due to rapid increased expression of P-selectin induced by thrombin or histamine, and later expression of E-selectin and ICAM-1 induced by lipopolysaccharide (LPS), interleukin 1 (IL-1),

tumor necrosis factor (TNF) and probably other stimuli. Chemotactic factors cause transient increases in adhesion on contact with neutrophils due to increased expression of β_2 -integrins, chiefly CD11b/CD18 (MAC-1). Since any chemotactic factors diffusing from the inflammatory site which cross the vascular endothelium and reach the blood are likely to be swept rapidly downstream, it is postulated that chemotactic factors must become attached to the luminal surface of endothelial cells at least transiently in order to do this. By these means, both surfaces, that of the endothelium and that of the neutrophil, increase their adherence to one another. Adherence is followed by transmigration across the endothelium and detachment from it by mechanisms which are still not entirely clear. This is followed by migration through the tissues to the site of injury by

a combination of chemotaxis, chemokinesis and contact guidance, as discussed in the article on chemotaxis. *In vitro*, neutrophils respond best (both by chemotaxis and chemokinesis) to many chemotactic factors at nanomolar concentrations or lower, but at higher (micromolar) concentrations locomotion is much slower. Thus cells at some distance from the injured site are fast moving and, as they reach the center of the gradient, they become slowed at the center of the lesion. Moreover, deposition of immune complexes, which bind to Fc receptors at the site of the lesion, also slows the cells by acting as an 'adhesive trap'. Also at micromolar concentrations of chemotactic factors, neutrophils are stimulated optimally to produce an oxidative metabolic burst, to secrete hydrolases and to ingest microorganisms. Thus the dose optima for locomotion and phagocytic events are arranged so that the cells perform these functions in sequence.

Chemotactic factors

Lists of chemotactic factors are given in Tables 1 and 2 under the Chemotaxis article, although there are many others which are not included. Many act on both neutrophils and monocytes/macrophages but not on lymphocytes. These include well-known factors such as C5a, formyl peptides and leukotriene B₄. More recently, studies of the chemokine family have shown that α -chemokines such as IL-8 are neutrophil specific, whereas β -chemokines are monocyte specific, thus providing a mechanism for the specificity of influx of inflammatory cells into different types of lesion.

It is important to emphasize that the term 'chemotactic factor' is inadequate to describe the actions of these factors. In locomotion assays their prime effect is always to stimulate locomotion, and the form the locomotion takes, i.e. whether it is directed or random, depends on whether a gradient is present or

not. But as well as effects on locomotion, these factors stimulate various metabolic and microbicidal activities of the cell (Table 1).

Formyl peptides are probably the most widely studied of all chemotactic factors. Formyl-met-leu-phe (FMLP) is the best-studied example but many related peptides have similar actions. They are putative representatives of release products from bacteria. Prokaryotic cells commence protein synthesis with a formyl-methionyl starter sequence which is later cleaved and may be recognized as a leukocyte attractant. There are probably many other prokaryotic chemoattractants which have not been defined, as most work has been concentrated on endogenously-derived attractants. The first of the latter to be defined was C5a, a peptide generated by complement activation which probably plays a major role in many inflammatory situations. Leukotriene B₄ (LTB₄) is generated by neutrophils themselves upon activation, and is likely to act as an amplifying device calling cells into sites of activation. Interest has centered recently on IL-8 and related chemokines, which are present at active concentrations in many inflammatory lesions, including those of rheumatoid arthritis and inflammatory lung disease, and which are produced by macrophages and other types of cells, including epithelial cells and vascular endothelial cells, usually following stimulation of these cells. Other cytokines such as TNF α and granulocyte-macrophage colony-stimulating factor (GM-CSF) also have chemoattractant activity for neutrophils. These are just as active as chemokines.

Chemotactic receptors and transduction systems

Receptors for formyl peptides, for C5a and for the chemokines all belong to the same family of serpentine, seven-membrane-spanning domain molecules, related to rhodopsin. These are linked to pertussis

Table 1

(a) Functions activated in neutrophils by chemotactic factors

Locomotion: chemotaxis; chemokinesis

Secretion: release of products of specific, azurophil, and other granules

Changes in cell adhesion: transient homotypic aggregation; longer term increase in adhesion to endothelium or to artificial surfaces

Increased microbicidal activity

(b) Effector biochemical events activated in neutrophils by chemotactic factors

Chemotaxis receptors: receptor redistribution to leading edge of cell; changes in receptor numbers or concentration-dependent changes in receptor affinity

Other events: increase in LFA-1 family surface receptors; increased actin polymerization; increased f-actin at leading edge; increased myosin-1 at leading edge; increased generation of superoxide (H₂O₂)

toxin-sensitive trimeric GTP-binding proteins containing a $G\alpha_1$ chain. Following ligand binding, these G proteins activate a phospholipase C, leading in turn to hydrolysis of phosphatidylinositol polyphosphates to form the second messengers, inositol triphosphate (IP_3) which, when released into the cytoplasm mobilizes calcium from internal stores, and diacylglycerol (DAG) which activates protein kinase C.

It is known that these are essential events for the activation of neutrophils by chemotactic factors, but a difficulty arises from the fact that these factors activate multiple functions in neutrophils. Most workers on signaling measure chemoattractant-induced metabolic activation or secretory events which are easier to quantify than locomotion, but which occur at higher ligand concentrations than those optimal for locomotion. Different signaling systems may be engaged at different ligand concentrations, and it seems probable that the different functions of neutrophils are signaled through different pathways. Locomotion can occur in the absence of calcium, either extracellular or intracytoplasmic, but this may simply reflect the possibility that there are back-up mechanisms for signaling. The essential requirements is to link the signal generated at the cell surface to actin polymerization so that a microfilament network can be formed which generates contractility and thus motility of the cell. It is likely that small G proteins such as p21 Rac as well as tyrosine kinases are involved downstream of the initial signal. It is also true that chemotaxis is signaled by cytokines which bind to receptors other than the serpentine receptors and these may use different signaling systems from the trimeric G proteins.

The polarity of the locomotor response should be emphasized. The response is polar in the sense that the cell does not behave as a unit but that different events are happening at the front of the cell, where recognition and response to chemotactic factors occurs, from those happening in the cell body. This is illustrated by experiments where the leading edge of a polarized neutrophil was detached from the cell body. These leading edge fragments contained cell surface receptors and actin filaments but lacked organelles or a nucleus. Such cell fragments continued to migrate and to detect chemotactic gradients. Conversely they lacked microbicidal activity, which depends on organelles which remain in the body of the cell. In neutrophils, polarization is initiated by events occurring at the leading edge of the cell, and many receptors, probably including chemotactic receptors, become selectively concen-

trated there. This edge of the cell is also rich in filamentous actin. As the cell moves forward, i.e. as a contraction wave moves from front to back, these events may sequentially involve the rest of the cell. A signaling system for an all-or-none event such as metabolic activation or secretion may be straightforward, but for locomotion over long distances in varying attractant concentrations it is probably more complex than we realize.

Clinical defects of neutrophil locomotion

Locomotor defects in neutrophils are rarely seen and poorly defined. The 'lazy leukocyte syndrome', described some years ago, is not a discrete clinical entity. Patients with leukocyte adhesion deficiency (LAD), due to a defect in the integrin β_2 chain and consequent defective adhesive function of β_2 -integrins, have neutrophils that show poor locomotion under circumstances where adhesion is required (e.g. on two-dimensional surfaces of in filters) but not where locomotion is adhesion independent (e.g. through collagen gels). LAD cells can polarize normally, which means that they recognize chemotactic factors normally. Neutrophils from Chédiak-Higashi syndrome have a chemotactic defect whose cause is unknown. A chemotaxis defect has also been reported in neutrophils with specific granule deficiency. In other reported abnormalities, the neutrophils are normal, but the patients have either circulating inhibitors of locomotion or are unable to generate endogenous chemotactic factors normally.

CHIMERISM, HEMATOPOIETIC

Yair Reisner, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The ancient Greek chimera, that awesome monster composed of different animals, has in modern times been tamed, and now represents a most desirable clinical status in recipients of organ transplants in general, and bone marrow transplants in particular. Thus, the term chimerism has come to represent a clinical status in which a graft of an organ from one individual is accepted and tolerated by the immune system of another. While acceptance of solid organs, such as kidney, heart or liver, is largely dependent on adequate suppression of the recipient's immune system, as well as on the degree of matching between donor and recipient histocompatibility antigens, bone marrow transplantation is unique in that, in most instances, incomplete or mixed hematopoietic chimeras are generated, and both host-type and donor-type blood cells can be detected in the recipient. Furthermore, while immune reactivity against donor type cells is an obstacle to bone marrow engraftment in all transplants, bone marrow transplantation is uniquely complicated by a second immune barrier, known as graft-versus-host disease (GVHD), mediated by donor type T cells reactive to host antigens.

A successful bone marrow transplant results in a state of hematological and/or immunological chimerism in which donor-type blood cells coexist permanently with host-type tissues, without manifesting alloreactivity to each other. If such a state of tolerance is achieved, subsequent organ grafts from the original bone marrow donor will be accepted without the need to further suppress the recipient's immune system. For this reason, investigation of the mechanisms of tolerance, as well as new and safer approaches for its induction, have challenged immunologists for over three decades.

Currently, bone marrow transplantation is mainly used as a rescue therapy following lethal radio-chemotherapy in patients with leukemia and other forms of cancer, but it can also be beneficial in the treatment of several nonmalignant hematological disorders and enzyme deficiencies.

The first demonstration that a bone marrow transplant could protect lethally irradiated animals from death came from the pioneering studies of Jacobson and colleagues and Lorenz and colleagues towards the beginning of the 1950s. However, it was only in 1956 that several laboratories independently confirmed that a cellular component of the transplanted

bone marrow protected recipient mice from the lethal effects of radiation, by its ability to generate new donor-type blood cells for prolonged periods of time.

A better understanding of the bone marrow cellular identity involved in radioprotection was achieved by Till and McCulloch, who discovered a correlation between the presence of spleen colonies in transplanted mice 8–12 days after bone marrow transplantation and the capacity of a given bone marrow cell suspension to protect lethally irradiated mice. This finding helped Trentin and Fohlberg to demonstrate that the entire repertoire of the hematopoietic system could be generated from a single spleen colony. By 1963, Becker and coworkers were able to use chromosome markers to demonstrate the clonal nature of spleen colonies. The existence of a pluripotent stem cell, and its importance in the protection of lethally irradiated mice, thus came to be postulated.

To this day, the characterization of the pluripotent hematopoietic stem cell has been the subject of intense research. With the identification of new cell surface markers, great progress has recently been made. However, since these cells have not been purified to a homogeneous state, they cannot be unequivocally identified in a bone marrow cell suspension.

Knowledge of the radioprotective properties associated with bone marrow transplantation found dramatic application in 1955, when five victims of the radiation accident in Vinca, Yugoslavia were flown to Paris and treated by Mathe and colleagues with bone marrow transplants. Due to technical problems in analyzing the origin of blood cells in these patients, interpretation of results was controversial, but it was agreed that, at best, some transient engraftment occurred, and could have helped the patients to survive, even though their own blood cells returned to normal levels. Fortunately for these patients, they did not suffer from GVHD, as the transplanted bone marrow did not engraft for a substantial period of time.

In the late 1960s, encouraged by the development of histocompatibility antigen (HLA) typing, it was felt that it might be possible to contain the severity of GVHD by transplanting bone marrow from matched sibling donors into patients with severe combined immune deficiency (investigated by Good and

colleagues) and leukemia (investigated by Thomas and colleagues). Both groups experienced many frustrating setbacks in their attempts to achieve stable chimerism, but it is primarily due to their perseverance that bone marrow transplantation has now become an integral part of the curative protocol used to treat such patients.

The duel between host-versus-graft activity and GVHD following bone marrow transplantation

The growing experience with transplantation of solid organs, such as kidney and heart, has clearly shown that it is possible to overcome graft rejection, and establish stable donor-type chimerism, when donors and recipients are appropriately matched for histocompatibility antigens and when adequate long-term immune suppression is maintained. Compared with other transplantable organs, however, cells in the bone marrow are highly antigenic, and recipients must first undergo a drastic immunosuppressive regimen of supralethal radiochemotherapy if the transplant is to succeed. In patients suffering from leukemia, as well as from other forms of cancer, this extreme conditioning serves to suppress adequately the recipient's immune system, as well as to eradicate pathological cells. However, despite the use of such intensive radiochemotherapy, administered in doses as high as the human body can tolerate, rejection of the bone marrow may still occur, in particular when poorly matched marrow is used for transplantation.

A second major immunological problem associated with bone marrow transplantation is the complication of GVHD, initiated by donor-type T cells capable of mounting an immune response against host-type antigens. In general, this reaction is directed against the skin, liver and gut, and is lethal in 10–15% of HLA-identical marrow recipients, as well as in over 40% of HLA-nonidentical marrow recipients.

During the 1970s, different laboratories demonstrated that removal of T cells from mouse or rat bone marrow by physical methods, by differential agglutination with lectins or by specific anti-T cell monoclonal antibodies, could effectively prevent the development of GVHD following transplantation of bone marrow allografts. In 1980, T cell-depleted mismatched parental bone marrow was successfully used for the first time to reconstitute the immune systems of infants suffering from severe combined immune deficiency (SCID). The growing international experience, with more than 100 such 'bubble children' to date, has shown that the use of this approach can allow successful bone marrow trans-

plantation across major histocompatibility barriers, thereby effectively curing this otherwise fatal disease. These cured patients have become 'split chimeras'. Their red cells, myeloid cells and platelets are generally of host origin, while their lymphocytes bear the donor type HLA phenotype. Moreover, since many SCID patients lack only T cells, the majority of B cells in these patients also remain of host origin. SCID patients are unique in that their immune response to donor cells is minimal. In these patients, therefore, the graft-versus-host (GVH) activity of T cell-depleted bone marrow can be studied with minimal interference from a host-versus-graft (HVG) reaction.

When T cell-depleted bone marrow was used to treat leukemia patients, however, results were disappointing, as residual immune cells and pathological cells which survived the intense conditioning regimen led to a markedly enhanced rate of graft rejection, as well as to a higher incidence of leukemia relapse in some types of the disease. Results from primate studies, later confirmed by analysis of peripheral blood lymphocytes (PBLs) from transplanted human leukemia patients, suggest that residual clonable T cells ($1-10 \times 10^6$ cells in the entire blood system) remain after completion of the supralethal conditioning protocol. Such cells more easily reject T cell-depleted bone marrow than unseparated bone marrow, as the latter contains about 1×10^9 donor-type T cells, an amount capable of outnumbering and destroying residual host T cells as well as leukemia cells. Thus, GVHD, which can be fatal, may also be beneficial, not only by paving the way for the engraftment of donor-type stem cells but also in its antileukemia effect (generally referred to as graft-versus-leukemia, GVL).

Altogether, although GVHD can be completely prevented in leukemia patients, the use of T cell-depleted bone marrow did not lead to an improvement in the overall long-term survival rate. Alternative methods, by which donor type T cells are partially suppressed by immunosuppressive drugs, such as cyclosporine A and methotrexate, seem to reduce the severity of GVHD and lower the risk of graft rejection and leukemia relapse. Thus, it may be possible to improve the therapeutic management of the 25–40% of patients for whom HLA-identical siblings are available. However, such methods cannot offer a solution for those patients who lack a matched sibling donor in the family.

Very recently, a novel approach to overcome the HLA barrier, employing megadose hematopoietic transplants, has been attempted successfully by Aversa and colleagues in mismatched leukemia patients. To achieve these megadose transplants, we

supplemented the conventional T cell-depleted bone marrow inoculum with CD34 peripheral blood progenitor cells obtained from the donor after the administration of recombinant human granulocyte colony-stimulating factor (G-CSF). The potent enhancement of engraftment which was experienced in these leukemia patients indicates that the massive number of infused stem cells may be capable of suppressing residual host cells which otherwise would mediate graft rejection. However, because only very miniscule numbers of T cells could be spared in these transplants, due to the marked GVHD risk associated with their HLA disparity, the T cell reconstitution in the engrafted patients is relatively slow.

Clearly, the question of whether the usefulness of T cells in promoting bone marrow engraftment and in conferring post-transplant immunity, as well as GVL effect, can be separated from their harmful GVH activity, has become a critical issue in bone marrow transplantation today.

Two independent studies have focused on this problem. The group of Tourain and our group showed that a transplant of non-GVHD-producing T cells from (donor $\times$ host) F1 mice could enhance long-term engraftment of allogeneic fetal liver cells or T cell-deficient 'nude' bone marrow cells, respectively. These results clearly suggest that T cells can enhance bone marrow engraftment in the absence of GVHD.

Although it is not yet known whether the T cell subpopulation responsible for this positive effect is separable from the T cell subpopulation which causes GVHD, recent studies have demonstrated that alloreactive T cells can be specifically contained *in vivo* by coblockade of the LFA-1:ICAM and CD28/CTLA-4:B7 pathways. Blazar and colleagues showed that hCTLA-4-Ig (inhibitor of the CD28/CTLA-4:B7 costimulatory pathway) plus LFA-1-specific antibody is highly effective in preventing GVHD induced lethality. Alternatively, Cavazzana and coworkers showed that specific elimination of interleukin 2 (IL-2) receptor-positive T cells, after allostimulation *in vitro*, can lead to attenuation of GVHD while maintaining a marked number of relatively nonalloreactive T cells. Both these promising approaches are being investigated in clinical trials.

Human-mouse hematopoietic chimeras

Successful xenogeneic bone marrow transplants between close species such as rat and mouse have in the past been demonstrated. Could human bone marrow cells be engrafted in lethally irradiated mice? This question is of particular relevance to acquired

immune deficiency syndrome (AIDS) research, as human immunodeficiency virus (HIV) does not cause AIDS in any other species except in humans, and it is believed that the presence of human CD4⁺ helper T cells is a prerequisite to infection. If such human-mouse chimeras could be created, they could provide a novel means by which to investigate the development of AIDS and leukemia, as well as for studies of human hematopoiesis.

The poor cross-reactivity between several human and mouse cytokines, as well as between other molecules involved in cellular recognition, was for many years believed to negate the possibility of producing human-mouse chimeras. In 1988, however, two independent studies involving the transplantation of human pluripotent stem cells into genetically determined immune deficient mice, such as the SCID mouse or the Bg/Nu/Xid mouse, documented for the first time the achievement of a transient split hematopoietic chimerism. Moreover, this xenogeneic chimerism was achieved without the apparent development of GVHD.

McCune and colleagues transplanted SCID mice with human fetal liver cells as a source of pluripotent stem cells void of GVHD, along with an additional grafting of human thymic epithelium under the kidney capsule. Thus, they were able to provide a human microenvironment sufficient for the development of human T lymphocytes bearing normal phenotypes. Such T cells remained in the peripheral blood of engrafted mice for 4-8 weeks, during which time they could be infected with HIV.

Kamel-Reid and Dick were able to engender transient myeloid engraftment in Bg/Nu/Xid immunodeficient mice by transplanting them with human bone marrow. Nine weeks after transplant, *in vitro* culture of bone marrow cells from these mice revealed the presence of human genetic material in early myeloid progenitors, suggesting that differentiation of human myeloid precursors can take place in such mice. Subsequently, this same murine model enabled the engraftment in Bg/Nu/Xid mice of pathological cells from human acute lymphocytic leukemia patients. More recently, Lapidot and colleagues identified a new human acute myeloid leukemia (AML)-initiating cell, which is less mature than colony-forming cells, by transplantation into SCID mice. These cells, which are CD34⁺ CD38⁻, home to the bone marrow and proliferate extensively in response to *in vivo* cytokine treatment.

Mosier's group further demonstrated that stable mixed lymphoid human-mouse chimerism could be established simply by intraperitoneal injection of human PBLs into SCID mice. Recently, they showed that donor T and B lymphocytes could be detected

in the peripheral blood of recipient mice several weeks later, without having caused GVHD. Such human-mouse chimeras could be infected with HIV. Several studies have shown that the engrafted human T cells in these chimera become anergic, unresponsive to stimulation with anti-CD3 or mitogens, and that the human T cell repertoire is limited to xeno-reactive clones.

Recently, Lubin and colleagues described a new approach enabling engraftment of human PBMC in normal strains of mice and rats, following split-dose lethal irradiation. Irradiated animals are initially converted into SCID-like animals by means of bone marrow transplantation from SCID donors and subsequently are infused with human PBMC. These chimeric animals allow an effective and rapid engraftment of human cells, enabling their functional study early after transplant. Moreover, a marked human primary and secondary humoral response, as well as vigorous antiallogeneic human cytotoxic T lymphocyte (CTL) response, could be generated in the human-BALB/c radiation chimera by immunizing them with foreign antigens and allogeneic cells, respectively. In addition, the marked immunodeficiency induced in these radiation chimera has recently enabled us to transplant human liver fragments under the kidney capsule in such mice and to induce hepatitis C viremia, so as to provide a new murine model for the study of hepatitis B and C infection.

More recently, engraftment of human cells was also enhanced in SCID mice within the first few weeks after transplant, by conditioning of the recipient mice and by using a large inoculum of human cells. Although these preparative regimens were associated with marked lethality, engrafted human lymphocytes exhibited human antibody production and T cell responses similar to those found in BALB/c radiation chimera.

Mixed lymphoid chimerism and organ transplantation

Mixed chimerism, in which both host and donor lymphocytes coexist in significant numbers, rarely develops following bone marrow transplantation. Generally, one cell type is overtly dominant, due to its increased potential to eliminate or to compete with the other cell type. However, stable, long-term mixed lymphoid chimerism can spontaneously occur in nature, as when stem cells from one of two dizygotic twins penetrate the bone marrow of the other twin by placental vascular anastomoses. With the development of DNA analysis, it is now known that following bone marrow transplantation in leukemia

patients, normal host lymphocytes can be detected in most transplanted patients even many months after the transplant. It is believed that in such long-term, stable chimeras, host and donor lymphocytes are not reactive towards each other.

Likewise it has been suggested recently that resident 'passenger' leukocytes of hemato-lymphoid origin that migrate from whole organ grafts subsequently establish systematic microchimerism that is essential for graft acceptance and for the induction of donor specific nonreactivity. This hypothesis has been based primarily on observations in organ transplant recipients in whom transplantation was under postoperative immunosuppression with FK506 and prednisone. More recently, attempts to enhance hematopoietic chimerism in recipients of organ transplants by using bone marrow transplantation from the organ donor under postoperative immunosuppression led to some improvement of solid organ acceptance. Nevertheless, enhancement of chimerism was still very limited and not sufficient to afford acceptance of organs in about 50% of the patients, even though they were treated with immunosuppressive drugs. Clearly, if post-transplant immunosuppression had been omitted in these patients, the results are likely to have been even less successful.

Though the mechanisms underlying the development of mutual tolerance have been studied for more than a decade, they are not yet completely understood, although great progress has recently been made in the molecular characterization of the T cell receptor structure, and the selection of its repertoire during thymic differentiation. It is interesting to note that once stable and substantial mixed lymphoid chimerism is established, transplantation of any other organ from the same donor will be accepted without further need for immunosuppression.

Since the early 1970s, many studies have involved attempts to achieve mixed lymphoid chimeras under conditions less severe than those employed in bone marrow transplantation of leukemia patients. Attempts to induce classical transplantation tolerance in sublethally conditioned animals have generally made use of donor bone marrow cells. Traditionally, in these studies more attention was dedicated to achieving lymphoid chimerism than a complete donor-type hematopoiesis. Pierce and colleagues have demonstrated that infusion of unseparated bone marrow cells, comprising GVHD-producing T cells, into sublethally irradiated allogeneic recipients results in mixed lymphoid chimera which were tolerant to donor-type skin grafts. This approach, shown to be mediated by Thy-1⁺ cells, is not only associated with a potential risk of GVHD, but is also limited to the lymphoid lineage due to the

insufficient myeloablation associated with the conditioning (3×2.5 Gy) regimen used. Further progress has been made by Cobbold and colleagues, who were able to induce, with T cell-depleted bone marrow, lymphoid chimerism in sublethally irradiated recipients conditioned with a nonmyeloablative regimen, including 6 Gy total body irradiation (TBI) and *in vivo* treatment with anti-CD4 plus anti-CD8. Likewise, Sharabi and Sachs demonstrated that transplantation tolerance can be induced after a very low dose of TBI (3 Gy) if the conditioning is supplemented with booster irradiation of the thymus with 7 Gy and with anti-T cell therapy, similar to that employed by Cobbold and coworkers. Again, mixed chimerism was only documented in the peripheral blood and was based on monitoring of donor-type cells within the Thy-1 positive and negative cells, whereas analysis of chimerism in the myeloid compartment in bone marrow or spleen is missing.

Very recently, Bachar and colleagues attempted to broaden the 'megadose' approach and to test whether large inocula of T cell-depleted mismatched bone marrow transplants can induce stable donor-type chimerism in sublethally irradiated mice. We addressed this goal, which represents a difficult challenge due to the marked number of host-type lymphocytes surviving the sublethal irradiation, by investigating whether escalation of the bone marrow cell dose can effectively promote the establishment of complete donor-type hematopoietic chimerism across full MHC barriers. Our results demonstrated that full donor-type hematopoietic chimera, which are stable for over 6 months in both the myeloid and the lymphoid lineages, can be produced by this approach in the bone marrow and in the spleen without any post-transplant immune suppression and in the absence of GVHD. Furthermore, anti-host antibody therapy, which was found to be necessary in previous studies, is not required and the marked numbers of residual host-type lymphocytes which survive 6.5 Gy TBI, are probably overwhelmed and paralyzed by the megadose transplant.

Future directions

Despite the importance of allogeneic bone marrow transplantation in humans, its use presently remains restricted to the treatment of fatal disorders such as cancer, SCID and aplastic anemia. A wider use of this curative approach is limited by the occurrence of GVHD if T cell purging is not used, and by the graft rejection associated with T cell depletion.

However, two major approaches to overcome these barriers, namely the use of B7-CD28 blockade or the use of megadose T cell-depleted transplants,

which have been proven successful in sublethally irradiated mice, lend the hope that the use of allogeneic hematopoietic stem cells will become safer in the near future, thereby expanding its use to the treatment of genetic disorders other than SCID, which are less acute but which can, nevertheless, be lethal over the course of years.

In addition, it is hoped that by the same approach, using nonlethal preparative regimens, induction of specific immunological tolerance towards donor-type antigens, as a prelude for transplantation of solid organs from the same donor, will also become possible.

Meanwhile, an alternative approach has captured the interest and imagination of both scientists and the public at large. Experiments in mice have shown that it is possible to insert a particular gene into the hematopoietic stem cell pool by means of retroviral vectors. It is hypothesized that a diseased bone marrow could be corrected *in vitro* by such 'gene therapy', and then reinfused successfully into the patient. By employing such an approach, the problems of GVHD or graft rejection could be entirely avoided. However, due to the low frequency of pluripotent stem cells in the marrow preparations, and the difficulty in stimulating self renewal of such cells *in vitro*, this new approach is still in the embryonic stages of development. If successful, we may have to define a new chimerism status in which transplanted cells differ from the host cells by a very minute piece of DNA.

An alternative approach to achieving hematologic chimerism involves replacing the bone marrow or peripheral blood stem cells with cord blood hematopoietic stem cells. In 1990, Gluckman and colleagues demonstrated for the first time that cord blood can correct Fanconi anemia in a matched sibling. Both the HLA and the disease-free status of the embryo were established by prenatal testing, and transplantation could be planned for before birth. Thus, the potential number of matched sibling donors in the family could be increased. Moreover, if large numbers of cord blood preparations could be collected and cryopreserved, it could potentially increase the availability of matched unrelated donors. While this possibility is gaining increasing enthusiasm worldwide, it is still hampered by a marked incidence of engraftment failure, associated with the limited number of hematopoietic stem cells which can be collected in cord blood. Clearly, the potential of this approach could be greatly enhanced if it were possible to expand the pluripotential stem cells *ex vivo*. Results in animal models regarding the self renewal capacity of expanded stem cell populations are encouraging but still controversial.

Finally, studies in animals have clearly demonstrated that hematopoietic chimerism can be achieved before birth by *in utero* transplantation of allogeneic stem cells. The success of this approach is based on the relative ease by which tolerance can be induced in the embryonic state, compared with in adults. In the future, it is hoped genetic diseases may be corrected *in utero*, thus eliminating the need for intensive conditioning protocols required for transplantation in adult recipients.

CHLAMYDIA, INFECTION AND IMMUNITY

Roger G Rank, Department of Microbiology and Immunology, University of Arkansas for Medical Sciences, Little Rock, Arkansas, USA

Characteristics of the organism and its antigens

The genus *Chlamydia* of the order Chlamydiales con-

sists of four species: *C. trachomatis*, *C. pneumoniae*, *C. psittaci* and *C. pecorum*. *C. trachomatis* is comprised of three biovars, two of which are natural parasites of humans and the remaining biovar a pathogen solely for mice. The two human biovars

are subdivided into 12 oculogenital serovars which are responsible for trachoma (serovars A, B, Ba and C) and genital infections (serovars D, E, F, G, H, I, J and K). Genital infections result in urethritis in males and cervicitis, endometritis and salpingitis, potentially leading to tubal obstruction, in females. The remaining three serovars (LGV 1–3) are responsible for lymphogranuloma venereum, a more aggressive and systemic genital infection. *C. pneumoniae* has recently been found to be a major cause of community-acquired pneumonia. Of even greater interest, *C. pneumoniae* has been found in association with atherosclerotic plaques in coronary artery disease. Whether this organism actually causes coronary artery disease has not been confirmed. *C. psittaci* and *C. pecorum* are diseases of veterinary importance although *C. psittaci* may cause a serious and potentially lethal zoonotic infection in humans. Phenotypic and genotypic differences are recognized among the *C. psittaci* but the taxonomic differentiation has not been clearly defined. A wide variety of animals, including but not limited to birds, ruminants, cats, and guinea pigs are infected with different biovars. *C. pecorum* is primarily a pathogen of swine although koalas have also been found to be infected.

Chlamydiae are obligate intracellular parasites and as such are incapable of replicating outside of a host cell, apparently depending upon the host pools for growth. They are able to infect a variety of host cells both *in vivo* and *in vitro* and survive intracellularly by preventing phagosome–lysosome fusion. Chlamydiae are unique among pathogenic bacteria in that they undergo a developmental growth cycle which consists of two stages. The elementary body (0.3 μm) is metabolically inert and is the infectious form of the organism. It attaches to the host cell via a mechanism(s) which is not yet clearly defined. Potential adhesins including the major outer membrane protein (MOMP) (≈ 40 kDa), a cysteine-rich 60 kDa protein (Omp2), and the 70 kDa protein have been suggested although binding via heparan sulfate and surface glycoproteins has also been proposed. After internalization within an inclusion vacuole, the elementary body differentiates into a reticulate body (1 μm) which is metabolically active and divides via binary fission. By 25–30 h after infection, reticulate bodies begin to differentiate back to elementary bodies. Ultimately, the host cell dies with the release of the elementary bodies which go on to infect other cells, the complete cycle taking approximately 40 h.

The major structural component of the chlamydial outer membrane is the MOMP, comprising about 60% of the outer membrane proteins. Rigidity is provided by extensive intramolecular disulfide bonds and the protein is folded so that four segments,

termed variable domains, are surface-exposed. These domains vary among different serovars of *C. trachomatis*, while the remaining regions are conserved among the serovars. MOMP contains genus-, species- and serovar-specific epitopes. Chlamydiae produce a lipopolysaccharide (LPS) which is also associated with the outer membrane and contains a genus-specific antigen. The LPS is immunologically and chemically related to the ‘deep rough’ (Re) mutant LPS of enteric bacteria. Also highly immunogenic are the Omp2 protein and the 57 kDa heat shock protein.

Immune responses of the host

Because chlamydiae infect a wide array of animal species as well as different anatomical species, it is difficult to define a single pattern of host response. There are undoubtedly similarities in the effector mechanisms involved in eliminating the organism, but the critical effector mechanisms appear to vary with the site of the infection, the host species, the particular strain of a host species, and even the infecting strain or serovar of the chlamydiae. The majority of our information regarding immune responses to chlamydial infections has been derived from *in vitro* studies and from genital, respiratory and ocular animal models of infection which can basically be divided into protective host responses and pathologic host responses.

In virtually all chlamydial infections, the initial host response is an acute inflammatory reaction consisting of polymorphonuclear leukocytes (PMNs) which can be chlamydicidal but also may be responsible for tissue pathology. The mechanism by which PMNs are attracted to the local site is not clear, but recent data have shown that by infecting epithelial cells, chlamydiae effect the release of interleukin 1 (IL-1) and IL-8, the latter being a powerful chemo-attractant for PMNs. Infection of macrophages by chlamydiae results in the lipopolysaccharide triggering the production of tumor necrosis factor α (TNF α), IL-1 and IL-6. Chlamydiae have also been shown to activate the alternative complement pathway. Thus, IL-8, TNF α , and complement can potentially mediate the chemotaxis of PMNs to the local site either directly or by upregulating the expression of ICAM-1. In studies in the murine model of genital tract infection, ICAM-1, VCAM-1 and MAdCAM-1, have been found to be expressed early in the infection and could be addressins which are responsible for the extravasation of PMNs and other inflammatory cells at the site of infection.

In both genital tract and respiratory murine models, natural killer (NK) cells have been found to

appear at the local site very early in infection, as early as 24 h after infection in the genital tract. The NK cells are the source of interferon γ (IFN γ) which has also been detected early in the infection and could play a role in the control of the infection until the acquired immune response develops. IFN γ has been shown to be chlamydiostatic *in vitro* and to drive the organisms into a nonreplicating state. TNF α has also been observed *in vitro* to inhibit the growth of chlamydiae. Some data suggest that IFN γ produced by NK cells may be important in the ultimate induction of a T_H1 response.

Both humoral and cell-mediated immune responses are elicited by chlamydial infection. In some models, it appears that antibody is important for the resolution of the infection. It has been well-documented that antibody can neutralize chlamydial elementary bodies *in vitro*. Passive immunization with antibody has met with varied success but at least in the *Chlamydia psittaci* strain GPIC:guinea pig model, serum immunoglobulin G (IgG) was actually able to reduce the level of genital infection. Specific IgA is commonly found at local mucosal sites in association with the development of infection and could play a role in the protective response, especially in chlamydial ocular infections. Cell-mediated immunity (CMI) has been found to be important in both murine and guinea pig models. In the mouse, CMI is solely responsible for the resolution of the infection, since B cell-deficient mice are able to recover normally from the infection, while nude mice and CD4 knockout mice do not resolve their infections. The majority of the evidence indicates that CD4 cells are the primary subset responsible for protective cell-mediated immunity. Adoptive transfer of CD4 cells, CD4-enriched lines and a CD4 T_H1 clone are effective in resolving chlamydial genital infections. Nevertheless, adoptive transfer of CD8 cells, CD8 cell lines and a CD8 clone can also resolve infections, albeit not as effectively as CD4 cells. In genital infections, the dominant CD4 subtype is the T_H1 cell, resulting in high levels of IFN γ and minimal levels of IL-4. IFN γ produced by CD4 and CD8 cells most likely plays a major protective role in the acquired immune response. While cytotoxic T lymphocyte (CTL) activity of CD8 cells has been described, their *in vivo* function has not been confirmed. Interestingly, in the primate models of eye and genital infection, equivalent numbers of CD4 and CD8 cells have been reported at the local site, while in the murine genital tract, the dominant cell type is CD4.

Immunity to chlamydial infections is short-lived in humans as well as animal models. In trachoma, the number of organisms isolated is reduced upon sub-

sequent infections, but pathology persists. There is evidence in the murine and guinea pig genital tract models that susceptibility to reinfection is associated with the loss of T cells in the genital tract. However, it also appears from studies in the guinea pig that reduction in the level of a challenge infection may be associated with the antibody response.

While animal models indicate that CMI is important in the resolution of and resistance to infection, it may also be a critical factor in the development of immunopathology. Trachoma has been clearly defined as a disease caused by repeated antigenic challenge and production of a delayed-type hypersensitivity response, even when few organisms can be isolated. Several animal models have also implicated a similar mechanism in fallopian tube damage resulting from multiple chlamydial genital infections. Of importance has been the observations by several groups that the course of infection may vary in different strains of mice and that different serovars of *C. trachomatis* may produce infections of differing severity. The reasons for the differing response among strains has not been clearly defined.

Evasive strategies by the organism

A key feature of chlamydiae is their unique replication cycle and their ability to replicate inside host cells. Obviously, growth intracellularly protects the organism to some extent from antibody although the elementary body is susceptible to neutralization. In order to survive in the host cell, the organisms have developed a mechanism for preventing phagosome-lysosome fusion. Nevertheless, the prevention of phagosome-lysosome fusion is overcome when chlamydial elementary bodies are opsonized by antibody. A potentially significant mechanism of host immune response invasion may be associated with the apparent ability of chlamydiae to remain in a persistent or latent infection state. Evidence for such a form has been provided by the detection of chlamydial DNA, RNA and antigen in the absence of organisms which could be isolated by standard technology. A variety of other data suggest that a latent form may be present. While the mechanism for latency or persistence has not been defined, it is interesting to note that IFN γ is bacteriostatic *in vitro* for chlamydiae, in that it prevents the organism from dividing. However, upon removal of the IFN γ , the organism again begins to replicate and to complete its growth cycle. It is tempting to speculate that the presence of IFN γ from NK or T cells drives the organism into a non-replicating form until the cellular source of IFN γ leaves the local site and thus brings about a decrease in IFN γ and its control of the infection.

Vaccines

Currently, there is no effective vaccine for chlamydial infections in humans, but a whole-organism vaccine has been available to the veterinary industry for years against the *C. psittaci* feline conjunctivitis organism and ovine abortion agent. An inactivated whole-organism vaccine against trachoma was tested in humans in the 1960s and was to some extent effective. However, the trials were discontinued when some individuals developed more severe disease. These data were supported by primate studies.

Recently, the thrust of vaccine design for chlamydiae has been aimed at determining the protective antigen. The major target for immunization because of its surface exposure and potential involvement in adherence has been the MOMP. The MOMP has been shown to have epitopes which elicit neutralizing antibodies, although to date, subunit vaccines have not been able to elicit protective immunity in animal models. It is important to note that purified MOMP has been found to be protective in animal models, but only if the protein retains its native conformation. Denatured or recombinant MOMP has not been found to be protective. Thus, it appears that with regard to the humoral response, protective antibodies are directed against conformational epitopes on MOMP. While MOMP appears to be the best target to date, there are other chlamydial components which may also be useful targets for a vaccine. Because *in vivo* data indicate an important role for

cell-mediated immunity, it will be important to develop a vaccine which also elicits a protective T cell response. Nevertheless, a major consideration in the development of a vaccine needs to be the possibility that the vaccine may actually elicit more severe pathology or that the vaccine may expedite the development of persistence. Thus, a successful vaccine for chlamydial infections may be one that prevents pathology, although it would be ideal to have a vaccine which prevents infection altogether.

CHROMOSOME TRANSLOCATIONS OF IMMUNE GENES

Kishor Bhatia and **Marina I Gutiérrez**, Lymphoma Biology Section, Pediatric Branch, National Cancer Institute, NIH, Bethesda, Maryland, USA

The uniqueness of the immune system lies in the immense diversity of the reactive proteins that the immune cells can synthesize. The immune genes, as we know now, are one exception to the notion that DNA is immutable. Indeed, the cutting and repasting of DNA segments in lymphocytes is necessary to provide the immune system the varied repertoire to discriminate between the vast array of antigenic moieties that an organism encounters. The reconfiguration of the 'germline' immune genes is achieved by the action of a normal recombination machinery that allows this process to be restricted to developing lymphocytes. This recombination program relies

upon nucleotide sequences in the recombining substrates to provide regional specificity to the cutting and repasting. The process of recombination is influenced by several other factors, including the regional organization of chromatin, the coordinated expression of the recombinase enzymes and the components in the nuclear matrix.

Although the recombinational program that provides for the DNA breakage and rejoining is monitored to prevent errors, some baseline of error-prone recombination may ensue. The probability that this instability will occur at a higher frequency is greater in cell lineages that are prone to such recombination.

It is easy to see how this error-prone recombination could juxtapose regions that are not meant to be ordinarily recombined. The consequences of such illegitimate recombination could range from none to severe depending upon the kind of substrates that recombine. For example, the accidental fusion of sequences that enhance transcription to genes that control proliferation, could result in uncontrolled growth. Thus, the occurrence of error-prone recombination, mediated either because of errors in selecting the sequences that need to be cut and ligated or because of errors in the configuration of the chromatin, is of significant consideration in both leukemogenesis and in lymphomagenesis.

Immune genes as substrates for recombination

The unrearranged immune receptor genes (immunoglobulin and T cell receptor) share the same basic organization – the genes are discontinuous. The chains of the immunoglobulin and T cell receptor (TCR) molecules are encoded as small segments (V, D, J and C) that must associate with each other to provide the complete coding sequence. The genes for the immunoglobulin heavy chain and for the light chains κ and λ are located on chromosomal bands 14q32, 2p12 and 22q11, respectively. The TCR genes are encoded on 7p11 (TCR γ), 7q34 (TCR β) and 14q11 (TCR α and TCR δ).

Recombinational pathway in the rearrangement of immune genes

During the process of generating a functional heavy chain, the intervening genomic DNA between the randomly selected D (diversity) and J (joining) segments is excised, bringing together the D_H and the J_H segments. This process is thought to occur simultaneously on both alleles. Following this rearrangement, a V (variable) region on one of the alleles is approximated to the DJ region to form the VDJ exon. The coupling of the VDJ regions is an imprecise mechanism which includes the insertion of a few extra nucleotides (N) and may result in an 'out-of-frame' rearranged gene. If so, the V region on the second allele is allowed to recombine to give the B cell a second chance to generate a productive allele, before undergoing apoptosis. The light chain and the TCR genes go through a similar VJ/VDJ rearrangement.

Normally, the mechanism of recombination necessary for the production of an immunoglobulin or a T cell receptor molecule allows intralocus recombination to assemble the VDJ regions of the immune genes. In B cells an additional recombination path-

Figure 1 The generation of a productive immune receptor gene is linked to the activity of the recombinase complex. The multi-step rearrangements of the immune locus that takes place during maturation of lymphocytes provides the 'window' during which error-prone recombination may result in a translocation that will allow the clonal proliferation of the cell that has undergone such a translocation. It is possible that normal monitors of the differentiation process that determine the suitability of the lymphocyte at each step also need to be neutralized in the cell with an immune gene translocation in order to resist apoptosis.

way, which again is intralocus, carries out the juxtaposition of the various constant regions to the rearranged VDJ region, allowing the Ig molecule to switch from IgM to any other class. A third pathway that provides additional diversity to the immune molecules is the hypermutation pathway.

Several factors subscribe to the catalysis of these recombination mechanisms. The recombinase machinery interacts with signal sequences on the two segments that need to be cut and pasted, which consist of a heptamer, defined by the consensus sequence CACAGTG, and a nonamer (GGTTTGT) present on each site. It seems reasonable that the substrates for the recombination should be accessible to the recombinase enzymes, thus it is likely that structural features, e.g. the chromatin structure, will mechanistically influence the recombination pathway.

Error-prone recombination: cause of chromosomal aberrations

Given the high frequency of all recombinational events in the lifetime of an organism it is likely that in some instances errors in the recombinase machinery will lead to interlocus rather than intralocus

recombination. The time window of such errors would, of necessity, mirror the time window in the cell lineages where recombinase machinery is active (Figure 1). The recombinational events that are more likely to result in such mistakes include the juxtaposition of the D to the J regions, the recombination of the V and the rearranged DJ region and the switch recombinations.

The occurrence of interlocus recombination within the same chromosome but involving relatively distant sites has been documented for the inversions of chromosome 14, between the immunoglobulin heavy chain and the TCR α genes, and of chromosome 7, involving the TCR β and γ genes. Interlocus recombination that involves two chromosomes has also been documented for the translocations that involve chromosomes 7 and 14 where there is a VDJ recombination that juxtaposes V γ to DJ δ or VD δ to J γ . It has been suggested that this interchromosomal event may occur at a frequency as high as 1×10^{-3} .

The possibility that the presence of a heptamer sequence alone may in some circumstances catalyze the locus to act as a substrate of recombinase albeit at a low frequency, increases the likelihood of recombination involving immune genes and nonimmune partners.

Chromosomal translocations in hematological malignancies

In several neoplastic entities, the development of a malignant phenotype has been intimately related to the gain of abnormal chromosomal patterns. Chronic myelogenous leukemia is the first disease in which an association with a consistent chromosomal abnormality (chromosome Philadelphia) was established. This results from a reciprocal translocation involving chromosomes 9 and 22. Subsequently, this translocation was also shown to occur in acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML) at low frequencies. The consequence of this t(9;22) is the expression of a chimeric protein that contains sequences from both the partner genes c-ABL (9) and BCR (22).

As can be seen in Table 1, the list of nonrandom chromosomal abnormalities in hematological malignancies has grown significantly. Several points can be made from cytogenetic correlations. In most cases there is a high specificity between the morphological classification and the presence of a given abnormality, e.g. the t(14;18) is specifically observed in follicular lymphomas. A more impressive correlation is the restricted involvement of chromosomal loci that harbor immune genes: 2p12, 7q34, 14q11, 14q32 and 22q11 in tumors of lymphoid lineage rather than

Table 1 The most frequent nonrandom chromosomal translocations in hematological neoplasms

in tumors of myeloid origin. Furthermore, there is a lineage dependency even among lymphoid malignancies for the immune loci involved. Thus, translocations involving 7q34 and 14q11 are restricted to T cell malignancies (Table 2) whereas translocations that involve 2p12, 14q32 and 22q11 are specifically associated with B cell neoplasms (Table 3). Since loci 7q34 and 14q11 harbor the TCR genes and in T cells these genomic loci undergo rearrangements, errors in recombination that allow interchromosomal translocations are targeted to these regions in T cells. A similar conclusion can be derived about translocations associated with the immunoglobulin genes in B cells. It is also significant that these immune

loci contain powerful transcriptional regulatory sequences. The major function of a mature immune cell is to synthesize immune molecules – immunoglobulin or T cell receptors – thus, recombinase-mediated rearrangements that will erroneously juxtapose genes that are normally silent in these cells will result in the forced expression of such genes. Depending upon the nature of the gene translocated, this deregulated expression of the rearranged gene could result in various phenotypic changes. If the phenotype conferred by the deregulated expression is survival advantage, it will cause a clonal expansion of the lymphoid cells with this particular rearrangement and provide a pool of cells that are prone to

MM, multiple myeloma

additional genetic insults, eventually leading to transformation.

There are two types of interlocus abnormalities that can be mediated by the VDJ recombinase: one that involves an immune loci as a partner and one that allows recombination between two nonimmune loci. Examples of the latter include translocations involving the MLL locus on chromosome 11q23 and an interstitial deletion on chromosome 1 which involves two independent transcription units, SIL and SCL, and allows the expression of SCL to be promoted by SIL regulatory sequences. In both these recombinations, it has been proposed that the regions of breakage and rejoining contain cryptic recombinase signal sequences and extra nucleotides, supporting the idea that these translocations are mediated by the recombinase machinery.

Chromosomal translocations that do not involve immune loci frequently result in the formation of novel chimeric fusion products and are not usually a result of recombinase errors. Examples of such translocations include the BCR-ABL and the ALK-NPM fusion products resulting from the t(9;22) and the t(2;5) respectively. The hybrid proteins may have unique biochemical properties that are not derived from their respective normal partner gene products, thus the chimeric genes result in a gain of function lesion that promotes leukemogenesis/lymphomagenesis. Thus, recombinational errors resulting in translocations could either promote malignancy via gene activation or via structural alteration, as

depicted in Figure 2. When immune loci are involved, the mechanism of tumorigenesis is likely to be of a quantitative nature and is limited to gene activation.

Pathogenetic mechanisms: contribution of translocations involving immune genes

A common theme in the molecular pathology of neoplasia is that tumor-associated genetic abnormalities provide the neoplastic cell with the ability to overcome the normal controls of homeostasis. There are three basic pathogenetic mechanisms: the abnormal expression of genes that result in cell proliferation, the silencing of growth inhibitory genes, or the loss of the ability of cells to self-destruct through programmed cell death (apoptosis). Frankly neoplastic cells accumulate more than one abnormality since multiple lesions allow the tumor cell to avoid or pass through the checkpoints present in normal cells that regulate such intricately balanced events as cell cycle, cell differentiation, cell migration and apoptosis. Cells which are lacking some essential attributes are diverted at these checkpoints for repair or self-destruction.

Translocations involving immune genes result in the abnormal expression of proteins either with respect to the cell lineage or the particular stage during differentiation or even with respect to the amount of protein synthesized. This deregulated expression may result from a positive influence – because of the juxtaposition of strong transcriptional regulators like

Figure 2 The recombinase machinery, which normally allows only intralocus recombination, is error prone and may cut and paste either two nonimmune genes (A), or juxtapose an immune locus with a nonimmune locus (B), by utilizing sequences present within these loci that serve as signal. If the recombinant product provides a survival advantage, the translocation will often be detected as a marker of clonal proliferation. The mechanisms by which the juxtaposition of an immune locus with a nonimmune locus or of two nonimmune loci provide a survival advantage are discrete. The former translocation often results in the formation of a fusion protein which carries some properties of both the partner proteins so that it acts as a novel protein. The latter translocation very often does not alter the expressed protein but nonetheless results in the inappropriate expression of this protein.

the enhancer elements present in the immune receptor genes, such as that which occurs in juxtaposition of *c-MYC* to *IgH* – or may result from loss of negative elements, e.g. the rhombotin 2 on 11p13 loses an upstream regulatory region during translocation with the TCR locus on 14q11.

The pathogenetic contribution of many, if not all, the translocations is the provision of a dominant genetic lesion. None of the translocations examined so far have resulted in the silencing of a growth-inhibitory or a tumor-suppressor gene product. The ultimate mechanism of lymphomagenesis or leukemogenesis is dependent upon the specific partner gene(s) involved in the translocation. The contribution of the immune genes appears mainly to be that of a switch to turn on the expression of the ‘oncogenic’ gene partners. As seen in Tables 2 and 3 four major classes of partner genes have been recognized: 1) genes that are master regulators of the expression of other genes (transcription factors); 2) genes that affect signal transduction mechanisms; 3) genes that

directly influence cell cycling and proliferation; 4) genes that affect cell survival.

Translocations that deregulate transcription factors
Among the various lesions that are a hallmark of oncogenic events, deregulation of those genes that themselves coordinate the expression of other genes are by far the most common of all lesions.

Transcription factors are versatile proteins that are essentially DNA-binding proteins. A common feature of these proteins is their modular structure which allows two unique domains to be independently defined, the DNA-binding domain and the transcriptional activation domain (Figure 3). The DNA-binding domain allows these proteins to specifically bind regulatory elements, through which they modulate gene transcription. Several classes of transcription factors have been identified as partners in translocations involving immune genes, these include the basic helix-loop-helix (bHLH) proteins, exemplified by *SCL*; proteins that contain zinc fingers (e.g. *BCL-6*), proteins with a cysteine-rich LIM domain like the rhombotin proteins (which also include a zinc finger-like structure), and proteins with specific leucine repeats termed as a leucine zipper, a domain that is found in the *c-MYC* protein; the *c-MYC* protein also contains a bHLH motif.

In translocations that involve immune genes and a transcription factor, the expression of these master regulators is deregulated. Since these genes themselves may control the expression of a set of genes that determine cell differentiation and proliferation, it is not surprising that such genetic lesions are oncogenic (Figure 3). In those translocations where the transcription factors are not juxtaposed to immune receptor genes, the deregulation of the transcription factor is often achieved by the formation of novel hybrid proteins where there is an exchange, for example, of the DNA binding domain conferring upon the hybrid protein an altered specificity of transcriptional regulation.

There appears to be a remarkable correlation between the specific type of transcription factor involved in the translocation and the progenitor cell lineage in which it occurs, suggesting strongly that these lesions disrupt regulatory cascades that control cellular differentiation programs. Thus, translocations involving *TCR β* and *LYL-1* are confined to pro-T ALL while those involving *HOX-11* are often seen in pre-T ALL.

In several cases these rearrangements have been directly correlated to mistakes in VDJ recombination. The ‘smoking gun’ for such mistakes include the presence of nucleotides inserted at the breakpoint junction and the identification of target heptamer-

Figure 3 Schema of a possible translocation in a pro-B cell. The translocation juxtaposes a powerful transcriptional regulator (TR), not otherwise expressed in this cell lineage, and an immune gene that is normally active in this cell lineage. As a result of the translocation the TR gains a powerful enhancer from the immune locus and is no longer subjected to lineage restriction. The out-of-lineage expression of the transcriptional regulator provides the switch to turn on other target genes initiating a cascade of events that leads to immortalization of this cell and eventually to neoplasia.

like sequences in the breakpoint region. Thus, recombinase errors have been demonstrated in translocations involving HOX-11 and SCL. One of the most common rearrangement involving SCL (1p interstitial deletions) occurs in as much as a quarter of all pediatric T-ALL and although it does not involve the immune genes, it is nonetheless presumed to be mediated by recombinases. This presumption is again based upon sequencing data that demonstrate the presence of extra nucleotides at the breakpoint junctions. The regions of chromosome 1 that are 'stitched' together also harbor heptamer-like recognition sequences, which catalyze erroneous recombination processes.

Translocations that induce an aberrant signal transduction pathway When the extracellular environment is conducive to proliferation, the cell orchestrates various sets of events that result in growth. This communication from the cell surface, which senses the environment through specific receptors, to the nucleus is transduced by pathways specific for a given signal(s). If the molecular switches within these pathways are locked in the 'on' position, the cell will play out all the downstream events and proliferate even in the absence of a signal.

Translocations that involve the immune genes and thereby dysregulate the signal transduction mechanisms include the t(7;9) (q34;q34) present in about 5% of T-ALL and resulting in a rearrangement of the TCR β locus with TAN-1, and the less frequent t(1;7) (p34;q34) which juxtaposes the LCK gene to the TCR β locus. The LCK gene product, which is a receptor tyrosine kinase homologous to the SRC protein, is predominantly expressed in lymphoid cells. TAN-1 is homologous to the *Drosophila* 'notch' protein which is thought to affect development and cellular differentiation. Unlike LCK, however, the expression of TAN-1 is not preferentially lymphoid. In addition to relocating TAN-1 under the transcriptional control of TCR β , this translocation results in decapitation of the gene, such that the 5' portion of TAN-1 is lost, permitting the redistribution of the protein from its normal location in the plasma membrane to the nucleus.

Translocations that cause a constitutively 'on' cell cycle switch The commitment to enter the cell cycle is an active process initiated by signals received from the extracellular environment. The cell can develop lesions within the cell cycle commitment program, such that it is induced to proliferate even in the absence of upstream signals. A critical phase of the cell cycle commitment occurs in G₁. Following commitment to cycle, several proteins are expressed early

in the G₁ phase. These include c-MYC, c-MYB, c-FOS, c-JUN and PCNA. The critical role these proteins play is highlighted by the observations that when expressed inappropriately, a large number of them promote cell transformation. Deregulation of the proto-oncogene *c-myc* by juxtaposition to an immune gene is seen in both B and T cell lymphomas. In B cell lymphomas, typically in Burkitt's lymphoma, this deregulation in most cases results from transposition of one allele of *c-myc* – normally present on chromosome 8 – into the Ig heavy-chain locus on chromosome 14. Breakpoint locations vary with respect to geography, thus endemic Burkitt's lymphomas very frequently have breakpoints far upstream of the *c-myc* gene, whereas sporadic Burkitt's tumors often carry breakpoints within the transcriptional unit of *c-myc*. It is possible that these breakpoints may be influenced by other factors like the presence of the Epstein-Barr virus, which in certain circumstances may actually influence error-prone recombinations involving the immune genes. Less frequently, the light-chain genes on chromosomes 2 and 22 are involved in deregulation of the expression of *c-myc* in B cell lymphomagenesis. In these cases the light chain genes are juxtaposed to a site downstream of the *c-myc* gene. In T cell lymphomas the deregulation of *c-myc* is achieved by juxtaposition with TCR α .

Among the several proteins that act in concert in allowing the normal progression of the cell cycle, the cyclins play a critical role. Cyclins are expressed transiently during specific phases in the cell cycle and then degraded. Key cyclins mediating G₁ transition are cyclins D1, D2, D3 and E. One error during DJ rearrangement may occur in precursor B cells, leading to a t(11;14) that gives rise to a low-grade B cell lymphoma classified as mantle cell lymphoma. The partner locus on chromosome 11, known as Bcl-1 or PRAD1, has homology to cyclin D1 which associates with CDK-4 and CDK-6. Following activation of the cyclin D/CDK complex, RB is phosphorylated leading to the release of E2F which is now available to transactivate genes like *c-myc*, *c-myb*, thymidylate kinase and thymidine synthetase that are essential for the G₁-S transition.

Death-defying translocations A reciprocal translocation between chromosomes 14 and 18 was found to occur frequently in follicular lymphomas. Molecular analysis indicated that the heavy-chain J segments were juxtaposed to a novel locus designated Bcl-2. The majority of breakpoints on chromosome 18 cluster in a short span of about 300 nucleotides termed as 'major breakpoint region' (MBR). Subsequently, another less frequent cluster of breakpoints was

identified 30 kb from the MBR and was designated as 'minor cluster region' (mcr). The translocation did not compromise the integrity of the open reading frame of the major transcript from the Bcl-2 locus. Detailed sequence analysis of the recombinational sites revealed the presence of extra nucleotides at the junctions of the derivative chromosomes suggesting an error mediated by recombinases. However, the actual recombination in this translocation may be catalyzed by chi-like sequence elements. Thus, the t(14;18)(q32;q21) may involve homologous recombination and errors in the action of the recombinases.

Functional analyses to elucidate the pathogenic contribution of the Bcl-2 gene provided insights into a fundamentally novel pathway in tumorigenesis. Aggressive uncontrolled proliferation of cells is one aspect of tumorigenesis, and accumulation resulting from a loss of susceptibility to dying is another pathway to neoplasia. Normal architecture is usually maintained within organs from early in embryogenesis, because all normal cells are subject to homeostasis. An important mechanism that contributes to this regulation is an inherent ability to selectively deplete cells. This ability is derived from the capacity of cells to activate pathways that result in suicide. These pathways are referred to as apoptosis. It is now apparent how the aberrant loss of this program in a cell in multicellular organisms can lead to neoplasia. The involvement of Bcl-2 in overcoming apoptosis suggested that the deregulation of this death-defying gene interfered with normal B cell ontogeny and prevented the otherwise normal loss of B cells due to programmed cell death. It now appears that resistance to death in several normal lymphoid cells relates to overexpression of Bcl-2. Recently, several other proteins with homology to Bcl-2 have been described. Although none of these members have been associated with chromosomal translocations, it is clear that several members of the Bcl-2 family interact with each other in orchestrating the cell death program.

Immune gene translocations associated with DNA repair deficiency

The cutting and repasting of DNA segments during the process of legitimate immune gene rearrangements must surely involve some components of the normal DNA repair machinery. Increased frequency of chromosomal aberrations are indeed observed in normal cells following severe DNA damage and in lymphocytes of individuals with a DNA repair deficiency. Several DNA repair deficiencies are also characterized by an increased risk of malignancies. Patients with ataxia telangiectasia (AT), for example,

are significantly prone to accumulating chromosomal aberrations and 10% of these patients demonstrate an abnormal karyotype in their peripheral blood lymphocytes. In a large proportion of these lymphocytes, the chromosomal aberrations are nonrandom and are often limited to breakpoints on 14q11, 14q32 and 7q34, loci that harbor immune receptor genes.

Molecular analyses have implicated TCR α , TCR β and IgH to be intimately involved in the recombinational processes that generate these aberrations. Translocations and inversions affecting chromosome 14 are the most frequent clonal rearrangements in AT lymphocytes. Some cases of AT clonal T cell expansion have been reported to progress to T cell leukemias. Interestingly, AT inversions that give rise to chimeric TCR are not associated with leukemogenesis, whereas the t(14;14)(q11;q32) or the inv(14)(q11;q32) clonal proliferations, both of which involve the TCL-1 locus, can progress to malignancy. In addition, some cases of T cell leukemias in AT patients carry a t(X;14)(q28;q11) which involves a locus termed as MTCP-1 and possibly the J region of TCR α .

Translocations involving immune genes in 'normal' cells

Several of the interlocus recombinations that involve immune receptor genes have also been observed in a small fraction of lymphocytes of healthy individuals. These recombinations include those that form hybrid immune receptor complexes by stitching together VDJ regions between different immune receptors genes. Our ability to detect these rearrangements suggests that they may be positively selected for. The finding that the hybrid receptors frequently recombine to be in-frame is in support of this argument. The analyses of these rearrangements (translocations or inversions) also suggest that they are mediated by the VDJ recombinases at a frequency of about 10^{-4} and predominantly involve chromosomes 7 and 14. It has been demonstrated that the frequency increases following exposure to pesticides. This increase is intermittent and reversible. Exposure to pesticides may also increase the risk of developing lymphoid malignancy. These observations, coupled with the increase of such rearrangements in AT patients, indicate that rearrangements involving immune receptor loci are subject to both exogenous and endogenous influences on DNA stability and that some of these rearrangements, for example the frequency of hybrid receptors, may serve as monitors of error-prone recombinase activity.

The functional consequences of these interlocus

rearrangements are not clear. At least one of the translocations described in lymphomas, the t(14;18) which juxtaposes the Bcl-2 locus within the transcriptional influence of the immunoglobulin heavy chain gene, has also been shown to occur in lymphocytes of healthy individuals, and also bears the 'signature' of recombinase activity. The frequency of this translocation increases with age and parallels the age-dependent incidence of follicular lymphomas. Whether this particular rearrangement is affected by exogenous influences such as exposure to pesticides is not known. However, its frequency is not increased in lymphocytes of AT patients. It is entirely possible that an error in recombinase will promote illegitimate recombination between interlocus immune genes more readily than between an immune and a nonimmune locus.

Summary

The principal function of T and B lymphocytes is to support the immune defense mechanisms of the organism. To do this effectively, these cells have acquired the capability of recognizing and neutralizing a diverse array of 'nonself' antigenic epitopes. This diversity is inherent in the germline structure of the immune genes, which contain several different regions. These discrete regions of the immune genes undergo several recombinational steps and reassortment of multiple segments to express the primary immune protein products.

The reassortment of the immune regions is achieved via a cutting and pasting mechanism that draws its specificity from the presence of specific nucleotide signal sequences, modulation of the accessibility of the genomic regions necessary for recombination, developmentally regulated expression of enzymes that will catalyze the recombination and possibly monitoring mechanisms that will prevent nonlegitimate substrates from recombining. In order to ensure the fidelity of the reaction, all productive recombinational processes are limited to be intralocus. Nonetheless there is a baseline error rate in the recombination process and some interlocus recombinations are also catalyzed. When these recombinations are catalyzed between immune and nonimmune partners, the expression of the nonimmune gene is deregulated. If the nonimmune partner is a growth-stimulatory protein, the recombinational

event can lead to a clonal expansion and eventually transformation of a lymphoid cell. As an extreme, these errors may also involve two nonimmune genes that contain nucleotide sequences that are similar to the recombinase signal sequences. Mistaken recombination of such partner genes may also be transforming if the two genes form a novel product with growth-stimulatory properties or if the expression of one of the growth-supporting partner genes is rendered lymphoid specific by the rearrangement. It is possible that the error-prone mechanisms by which these lymphoid-specific transformation events occur may also overlap with errors in other mechanisms that cause genetic instability and promote transformation of nonlymphoid tumors.

CHRONIC ACTIVE AND AUTOIMMUNE HEPATITIS

Early descriptions

Autoimmune hepatitis (AH) is now the preferred name for the disease originally described as chronic active hepatitis (CAH) in the 1940s in reference to a protracted viral hepatitis among military personnel. However, CAH, as later understood, emerged from descriptions in the 1950s of a relapsing or progressive and usually fatal liver disease of young women of no ascertainable cause, but perhaps the result of subclinical viral hepatitis. Emphasis was given to endocrine abnormality, amenorrhea, striae and acne due to the diseased liver failing to metabolize steroid hormones, and to hyperglobulinemia with reversal of the albumin–globulin ratio in serum, a then popular liver functional index. Autoimmunity was later implicated because of findings of lupus erythematosus (LE) cells in the blood, and a positive serum complement fixation test with human tissue homogenates as antigen. Clinical and serological resemblances between CAH and systemic lupus erythematosus (SLE) led to the name lupoid hepatitis, but the full expression of SLE was seldom seen, and the LE cell test was usually weaker and more transiently positive. Immunofluorescence testing in the 1960s for antinuclear antibody (ANA) replaced the LE cell test. Later, a serological reaction with smooth muscle was recognized as another identifying marker.

Heterogeneity of CAH

It was realized in the early 1970s that ‘chronic active hepatitis’ was a generic term for a liver disease with a variable expression and etiology. The hepatitis B surface antigen (HBsAg) had been identified as a marker of infection with hepatitis B virus (HBV), so that some cases of CAH could be characterized as HBV-associated CAH, in addition to autoimmunity and other causes.

Several categories of CAH can now be listed, as follows: 1) The archetypic CAH described in the 1950s as lupoid hepatitis, and now identifiable by autoimmune serological markers; 2) CAH due to persistence of hepatitis B virus (HBV) in the liver, marked (usually) by the presence of HBsAg in serum; 3) CAH due to persistence in the liver of hepatitis C virus (HCV); 4) CAH due to persisting immune-

mediated hepatic reactions to a drug; 5) histological CAH in accompaniment with liver diseases of known toxic, genetic or metabolic cause; 6) a category with neither autoimmune nor viral markers, nor any identifiable cause, referred to as ‘cryptogenic’. The relative frequency among populations of these categories of CAH varies. Chronic active hepatitis due to virus infection (HBV, HCV) is now numerically more frequent overall than the autoimmune type and, in some localities, virus-related CAH is seen almost exclusively.

General features of CAH

Chronic hepatitis ranges from an asymptomatic disease recognized only by biochemical abnormalities to one that is severe and progressively cirrhotogenic. Some cases of autoimmune hepatitis can have a long asymptomatic preclinical course, as pertains for other autoimmune disorders. Likewise, an insidious onset and clinical latency is usual for CAH associated with infection with HCV and, in many instances, with HBV. Cases of chronic active hepatitis will have some common general features related to liver dysfunction or cirrhosis, whatever the cause, and other features related to the individual etiological agent or process.

The general features include symptoms of hepatitis, including nausea, anorexia, jaundice, hepatosplenomegaly, and biochemical evidence of liver parenchymal damage, in particular high levels of transaminase enzymes in serum. The biopsy of the liver may show either of two histological lesions, named as chronic *persistent* hepatitis which is indolent and nondestructive, or chronic active hepatitis in which the main morphological feature is the disruption of the peripheral limiting plate of the liver lobule, with a periportal ‘spillover’ of the inflammatory exudate into the liver parenchyma: ‘piecemeal necrosis’ (Figure 1). This lesion generates scarring and eventually macronodular cirrhosis (Figure 2). Hepatocellular carcinoma is a frequent late sequel in CAH due to chronic virus infection but is seldom seen in autoimmune hepatitis. There are features unique to each of the individual categories, as indicated below.

Figure 1 Histological appearance of liver biopsy specimen from a female aged 65 years with recent-onset autoimmune hepatitis, showing periportal and lobular hepatitis and extensive hepatocellular necrosis (HE $\times 200$).

Figure 2 Liver from a female aged 45 years with autoimmune hepatitis, showing scarring and a coarse macronodular cirrhosis.

Features of specific types of CAH

Autoimmune hepatitis

Diagnostic criteria are currently being developed for autoimmune hepatitis. Characteristics that provide a 'disease profile' are: seronegativity for viral markers; female sex; northern Caucasian ethnic origin; multi-system disease expression (arthritis, rashes, thyroiditis, hemolytic anemia, ulcerative colitis); histologically large areas of periportal necrosis and prominence of plasma cells; pronounced hypergammaglobulinemia, $>30 \text{ g l}^{-1}$; serum autoantibodies; HLA-B8, -DR3 and -DR4; rapid response to, and dependency on, corticosteroid drugs; and 'resistance' to hepatocellular carcinoma compared with other types of chronic hepatitis or cirrhosis. Most weight attaches to the autoantibody markers, which are predominantly to antigens of nuclei and smooth muscle

(Figure 3). The multiple nuclear antigenic reactants include DNA (rarely), histones and lamins, and the smooth muscle reactant is the cytoskeletal filament, F-actin. Autoantibody to neutrophil cytoplasmic antigen (ANCA) is also seen. In a variant now called autoimmune hepatitis type 2, the marker antigen is enriched in liver and kidney microsomes (LKM). The LKM antigen has been identified as a particular cytochrome P450 isoform, CYP450 2D6. There is suspected to be a liver-specific autoantigen, perhaps membrane-associated, and one candidate is the asialoglycoprotein receptor (ASGP-R); however this to a degree lacks fine disease specificity for association with autoimmune hepatitis. Long-term treatment with prednisolone, combined with azathioprine, is highly effective.

Figure 3 Serological reactions in type 1 autoimmune hepatitis. Top left, lupus erythematosus (LE) cell as the former marker of antinuclear antibody (ANA); top right, homogeneously reactive ANA by immunofluorescence on Hep2 cells; bottom left, smooth muscle antibody (SMA) by immunofluorescence on mouse stomach; bottom right, F-actin specificity of SMA on cultured fibroblast showing staining of cytoplasmic microfilaments.

HBV-associated CAH (CAH-B)

HBV is a DNA virus that is parenterally transmitted. The frequency of chronic infection is higher in males and in localities in which HBV infection is endemic. Infection with HBV is acquired neonatally from infected mothers in high endemicity regions, and sporadically as a parenteral infection in low endemicity regions. The diagnosis of HBV-associated CAH (CAH-B) depends on detecting antigens of HBV in serum, the surface 's' antigen (HBsAg), and in early cases the 'e' antigen (HBeAg). In liver cells, HBV as the core antigen (HBcAg) is demonstrable immunohistochemically or by nucleic acid hybridization. CAH-B has a variable clinical expression and, although often indolent, undergoes progression to cirrhosis, and there is a clear predisposition to supervening hepatocellular carcinoma. Treatment with type 1 interferons may eliminate the virus and arrest the disease.

HCV-associated CAH (CAH-C)

HCV-associated CAH, which accounts for most examples of previously called non-A, non-B viral hepatitis, is due to an RNA virus which is transmitted parenterally. Formerly transmission was mainly by blood transfusion or treatment of hemophilia by blood products; currently the main routes are contaminated equipment of intravenous drug abusers, or close intrafamilial contact. Persisting infection with HCV is frequent after an acute infection. HCV-associated CAH (CAH-C) usually progresses silently to cirrhosis, and primary hepatocellular carcinoma is a risk in the later stages. Cirrhosis and hepatocellular carcinoma appear to be potentiated by coexisting alcoholic liver disease. Many cases formerly specified as cryptogenic CAH

(see below) will probably be attributable to infection with HCV. The diagnosis depends on serologic demonstration of antibody to antigens of HCV, or amplification of viral sequences in blood or liver tissue by the polymerase chain reaction. Treatment with type 1 interferons arrests infection in a proportion of cases. Some instances of CAH-C are associated with low-titer anti-LKM reactions, but this reactivity is not regarded as signifying that autoimmunity plays any role in their pathogenesis.

Drug-associated CAH

Various drugs, of which well-known examples include halothane and chlorpromazine, induce (infrequently) acute idiosyncratic hypersensitivity reactions affecting the liver, with hepatic or cholestatic expressions. As an accompaniment of these reactions, there may be demonstrable serum autoantibodies of the type usually seen in autoimmune liver diseases, directed to antigens of nuclei (ANA), smooth muscle (SMA), mitochondria (AMA) or liver microsomes (anti-CYP450 2D6). In cases with a protracted course, the histopathology of the liver resembles that of autoimmune CAH. However, characteristically, the disease resolves when the offending drug is withdrawn, and cirrhosis seldom eventuates. The immunopathogenesis of drug-induced CAH is uncertain.

'Toxic-metabolic' CAH

Histologically evident CAH may be seen in cases of chronic liver disease with a defined metabolic cause including alcohol abuse, or effects of inborn genetic errors including α_1 -antitrypsin deficiency, Wilson's disease or hemochromatosis. This category is relatively unimportant in terms of immunology, and features of the associated disease are dominant.

Cryptogenic CAH

This term is used for cases of CAH that are negative for markers of autoimmunity or infection with HBV or HCV and for which no other cause is ascertainable. Some cases may be attributable to infection with hepatitis viruses of which markers are absent from serum, to infection with as yet unidentified hepatitis viruses, or to autoimmunity wherein autoantibodies are no longer demonstrable.

Experimental models of CAH

Animal models of CAH of varying fidelity are recognized. HBV-associated CAH has the best models, represented by natural infections of animals in the wild, e.g. wood-chucks or ducks, with a 'hepadna' virus similar to human HBV. Models of autoimmune hepatitis have been induced by neonatal thymectomy and/or immunization with liver preparations, or by other techniques, but none so far has entirely simulated the naturally occurring human disease.

Liver-specific autoantigen

A liver-specific autoantigen as the target for immune-mediated damage in autoimmune hepatitis has not yet been identified. Crude preparations of liver cells and liver cell membrane preparations have been examined in various ways for reactivity with serum or peripheral blood T cells from patients with autoimmune hepatitis with promising but not unequivocal results. No liver-specific autoantigen has yet been identified by techniques applied successfully in other autoimmune disease, namely immunoblotting on electrophoretically separated liver cell membrane preparations, or probing gene expression libraries, using serum from cases of autoimmune hepatitis. Claims for ASGP-R as a liver-specific autoantigen relevant to autoimmune hepatitis need more substantiation.

Mechanisms of hepatocellular damage

The mechanisms of hepatocellular damage in chronic active hepatitis will vary according to the particular cause. In CAH-B there are two likely processes, a specific immune deficiency to critical antigens of the virus, probably the surface antigen, that allows a state of tolerated infection to occur, and a noneliminative attack by cytotoxic T cells on epitopes of the core antigen (HBcAg) expressed with class I major histocompatibility complex (MHC) molecules on the liver cell membrane. In CAH-C, the cytotoxic T cell attack would be on epitopes of HCV expressed with

class I MHC molecules on the liver cell membrane. In autoimmune hepatitis the suspected but as yet unknown processes include a T cell-dependent cytotoxicity due to cytokines released from CD4 T cells or cytotoxic effects of CD8 T cells, and an immunoregulatory failure permitting responses to tolerated hepatocellular autoantigens. Whether any pathogenetic connotations can be ascribed to the serologic reactivities, ANA, SMA, anti-LKM, that serve as disease markers is uncertain. It is intriguing that LKM autoantibodies in type 2 autoimmune hepatitis are highly focused towards one particular isotype (2D6) of CYP450, and that there have been identified linear autoepitopes on this enzyme, with the main site (WDPAQPPRD) at residues 262–270; also, a conformational epitope is suggested by the capacity of anti-LKM to inhibit CYP450 enzyme activity. Pathogenicity of the autoantibodies could depend on their cellular penetration, or the cell surface expression of the autoantigens, which remain under debate.

A final common immunocytotoxic pathway in CAH

The occurrence of autoantibody to various liver cell constituents, together with histological appearances of CAH in diseases that are not primarily attributable to an autoimmune process, has led to the idea that an immune-mediated attack on liver cells can supervene as a 'final common immunocytotoxic pathway' in liver diseases with different initiating causes. Whilst this may indeed occur, the features of this postulated 'secondary' autoimmune hepatitis do not really simulate those of the primary disease. Accordingly it is recommended that autoimmune hepatitis be regarded as an entity *sui generis* for which the nature should be better understood if and when a disease-specific and tissue (liver)-specific autoantigen is identifiable.

CHRONIC GRANULOMATOUS DISEASE

Anthony W Segal, Department of Medicine, University College London, Rayne Institute, London, UK

Chronic granulomatous disease (CGD) is a syndrome, the uniting features of which are a predisposition to infection, often with otherwise relatively nonpathogenic organisms, a granulomatous tissue reaction and impaired activity of the 'respiratory burst' of phagocytic cells. Although relatively rare, this syndrome has been the focus of intense investigation because it provides an excellent model for the examination of the mechanisms by which phagocytic cells kill and digest microbes, and has been central to our understanding of the structure and function of the NADPH oxidase electron transport chain, components of which are defective in the different subtypes of the disease.

NADPH oxidase of phagocytic cells

The uniting feature of CGD is an absence of the NADPH oxidase activity of professional phagocytic cells. When these cells engulf particles or are activated by a variety of stimuli, including the tetrapeptide formyl leucyl methionyl phenylalanine or the protein kinase C activator, phorbol myristate acetate (PMA), an intense burst of oxygen consumption is observed. This respiration is not mitochondrial, and is not required for the engulfment of microbes, but is important for the efficient killing of a variety of bacteria and fungi, both those classified as pathogenic, and normal commensals. In classical CGD this respiratory burst is completely defective, whereas in a few very rare cases, termed 'variant CGD' a small amount of oxidase activity can be detected.

Composition of the NADPH oxidase

The oxidase system is an electron transport chain that shuttles electrons from NADPH, generated by the hexose monophosphate shunt from glucose, to oxygen in the phagocytic vacuole. The only functionally defined component of the system is a very unusual flavocytochrome *b*, flavocytochrome *b*558. The flavin part of the molecule binds the NADPH and has strong homology with the FNR family of reductases. There are two hemes, which are unusual by virtue of their very low redox potential ($E_m = -225$ mV and -265 mV). It is composed of a 22 kDa subunit (α subunit, or p22^{phox}) and a 76–92 kDa heavily glycosylated subunit (β subunit, or gp91^{phox}). gp91^{phox} is the location of the FAD and NADPH binding sites and most probably both of the hemes. This cytochrome is located in the plasma membrane and membrane of the specific granules, and moves into the wall of the phagocytic vacuole as this forms.

A number of components of the oxidase have been identified; 40 kDa (p40^{phox}), 47 kDa (p47^{phox}) and a 67 kDa (p67^{phox}) proteins are located in the cytosol of the cell and move into association with the cytochrome in the membrane upon activation of the system. A small GTP-binding protein, p21^{rac} seems to be important for activation. The function of these molecules remains to be determined.

Molecular pathology

Chronic granulomatous disease is a syndrome in which the uniting feature is the complete absence of NADPH oxidase activity. The molecular pathology varies, but most cases fall into two main groups.

Approximately 70% have an X-linked pattern of inheritance and 30% are autosomal recessive.

X-linked

In almost all these patients flavocytochrome *b558* is missing from their cells and the lesion is in the gene coding for gp91^{phox}.

Autosomal recessive

The cytochrome is normal in these patients but they are unable to transport electrons on to it from NADPH. Their lesion has been shown generally to involve the p47^{phox}, which is undetectable in their phagocytes. p22^{phox} and p67^{phox} are missing in a minority of patients with this pattern of inheritance. No lesions involving p40^{phox} have been described.

Variant CGD

Unusual subjects have been described in whom a variable but small (less than 20% of normal) amount of oxidase activity can be detected. They are largely X-linked and have reduced expression of the large subunit of the cytochrome.

Clinical features

The respiratory burst of phagocytes is required for the optimal killing of a wide variety of bacteria and fungi. In its absence the microbes are engulfed but killing is impaired. This manifests in the patients in an increased frequency of infection, predominantly in the reticulo endothelial system. The most common sites include cervical lymph nodes, lungs, bone marrow (leading to osteomyelitis), liver and skin. *Staphylococcus aureus* is by far the most common infecting pathogen, although a wide variety of otherwise relatively avirulent organisms, for example *Serratia marcescens* can cause serious infections in these subjects. CGD must be excluded in children presenting with cervical or inguinal adenitis, liver abscesses, or aspergillus or nocardia pneumonia.

The defective function of phagocytes from these patients is not limited to their failure to kill microbes. Digestion by these cells is also grossly defective. This results in the diffuse development in the tissues of the granulomas that have lent their name to this syndrome. Granulomas in biopsies from these patients often result in an incorrect diagnosis of tuberculosis being made. Abnormal digestion and the granulomatous response result in poor healing, with the breakdown of wounds and chronic sinus formation. Exuberant attempts at healing can result in narrowing and obstruction of hollow muscular organs like the duodenum and urinary system. Chronic

inflammation of the gut may mimic inflammatory bowel disease, particularly Crohn's disease, where bowel disease is associated with the presence of granulomas in histological sections.

Diagnosis

The simplest and most rapid test for CGD is the NBT (nitroblue tetrazolium) test. Neutrophils from a small sample of peripheral blood are activated to produce superoxide which is detected by the NBT, which is converted from a yellow water-soluble compound to a dark-blue insoluble formazan that can be clearly detected microscopically. This slide test can be useful for detecting the X-linked type of disease in which the carrier mothers have a mosaic of normal and abnormal cells in their circulation. The respiratory burst can be accurately quantitated by measuring oxygen consumption with an oxygen electrode or superoxide generation by the reduction of cytochrome *c* in the presence and absence of superoxide dismutase. Immunological and molecular biological reagents are becoming available for the characterization of the nature of the defect in terms of the proteins and genes that are defective in each case.

Treatment

The prophylactic use of antimicrobial agents, in particular co-trimoxazole (a compound of trimethoprim and sulphamethoxazole) has transformed the natural history of this condition from one of frequent, life-threatening infections to that resulting in an almost normal life.

Infections that do occur must be treated aggressively with antimicrobial agents. Infusions of neutrophils should be used in addition in severe or systemic infection.

CIRCULATORY SYSTEM INFECTIONS

James P Burnie, University of Manchester, Manchester, UK

The most important infection involving the circulatory system with immunologic sequelae is infective endocarditis. The annual incidence in the USA and the UK is approximately 6 per 100 000 inhabitants, with an overall mortality of 15–30%. In acute endocarditis, most commonly due to *Staphylococcus aureus*, there is a high fever and, if untreated, a fatal rapid destruction of the heart valves. In subacute endocarditis there is a more indolent course and it is here that the immunologic complications occur. These may in part be due to emboli breaking off from the infected heart valve. Clinically these include splinter hemorrhages, Osler's nodes, Janeway's macules, glomerulonephritis, conjunctival hemorrhages (Roth spots) and clubbing of the fingers.

The major causative group of microorganisms is the streptococci. These can be subdivided into the relatively antibiotic-sensitive viridans streptococci and the more antibiotic-resistant enterococci. The viridans streptococci originate in the mouth and are defined by producing partial hemolysis on blood agar plates. They include *Streptococcus sanguis*, *S. mutans* and *S. salivarius*. The enterococci originate in the bowel and include *Enterococcus faecalis*, *E. faecium* and *S. bovis*. The last is associated with underlying bowel pathology.

Immunologic studies

The definitive diagnosis of endocarditis is dependent on the demonstration of vegetations on a heart valve at surgery or necropsy, or a peripheral embolus. Recently this has been augmented by a secondary set of clinical criteria. This consists of major criteria (positive echocardiogram and typical blood culture) and minor criteria (predisposition, fever, vascular phenomena, hematological phenomena, suggestive echocardiogram and suggestive microbiology). In

addition to this there is increasing literature showing that antibody levels, as measured by immunoblotting, are very high in enterococcal or streptococcal endocarditis and that these are species specific. For example, there is a strong immunoglobulin M (IgM) and IgG response in patients with *E. faecalis* endocarditis to an 88–90 kDa band identified as a homolog of heat shock protein 90. In *S. mutans* endocarditis there is an endocarditis-specific pattern of IgM, including antibody against a 190 kDa homolog of the Pac protein of *S. mutans* and the Spa protein of *S. sobrinus*. *S. mutans* antigen I/II (Pac homolog) has been implicated in the bacteria's adherence to teeth surfaces. Furthermore, monkeys immunized with the protein were protected against dental caries. The viridans streptococci have recently been demonstrated as being not only a cause of endocarditis but also a cause of septicemia in cancer patients. There have been changes in the taxonomy which have led to the emergence and description of *S. oralis* both as an important pathogen in neutropenic cancer patients and in infective endocarditis. Studies of the antibody in these diseases have defined two antigens as immunodominant. One of these has been cloned and demonstrated to be a homolog of the Pac protein of *S. mutans* and the Spa protein precursor of *S. sobrinus*. The protein has been further epitope mapped, demonstrating areas to which antibody was seen only in patients with endocarditis due to *S. oralis*. Human recombinant antibodies have been raised against these epitopes and shown to have some therapeutic activity in an animal model of infection. The second immunodominant endocarditis-specific antigen identified was an hsp90 homolog with an apparent molecular weight of 85 kDa. Similar specific antibody patterns have been shown in *Candida albicans* endocarditis, *Corynebacterium jeikeium* endocarditis and endocarditis due to *S. lactis*. In contrast, in

patients with staphylococcal endocarditis the level and pattern of antibody, as measured by immunoblotting, could not distinguish between cases and controls.

In all of the above the antibody patterns were specific to patients with endocarditis and the level of IgM correlated with disease. The resolution of infection by appropriate antibiotic therapy saw a rapid reduction in IgM levels when samples were measured weekly. The description of these patterns has led to a further study in which they were used as a way of diagnosing culture-negative endocarditis. This is a syndrome in which the patient has proven endocarditis but consistently negative blood cultures. Negative serology was found in 28 patients where the diagnosis of endocarditis was rejected or, if proven, staphylococcal, yeast, gram-negative, systemic lupus erythematosus, due to Q fever or *Chlamydia psittaci* or nonbacterial thrombotic. Positive serology was found in 27 of the 34 patients where the response to antibiotics suggested streptococcal or enterococcal infections. In 22 of these there was objective evidence of endocarditis. Positive serology was also found in three out of four further patients with vegetations at necropsy.

In summary, the diagnosis of endocarditis, both positive and negative, has been helped by the study of antibody levels. Individual antigens are now being identified and their role in the pathogenesis of infection characterized.

CLONAL DELETION

John H Russell, Department of Molecular Biology and Pharmacology, Washington University School of Medicine, St Louis, Missouri, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Clonal deletion refers to the process of eliminating unwanted clones of cells by death of the progenitors. At different points in development, the process eliminates lymphocyte (B and T cell) progenitors either through the stimulation or failure to stimulate their clonally unique, membrane-bound antigen receptors. Clonal deletion is an important, general mechanism to limit the development and expansion of auto-reactive lymphocyte populations that would cause autoimmune disease (Figure 1). Clonal deletion may also play an important role in limiting the organism's response to tumors.

Our early understanding of the interaction between pathogens and lymphocytes relied on the 'selective' expansion of appropriate lymphocyte clones in response to antigenic challenge. This allowed the maintenance of a pool of precursor lymphocytes to a broad range of pathogens that could be expanded through proliferation of the most appropriate clones for a specific pathogenic challenge. The lymphocyte clones with the highest affinity for pathogenic antigens would be selected for expansion because their receptor stimulation was the most effective. The paradoxical notions that antigen receptor stimulation could lead to nonresponsiveness through death (clonal deletion) or anergy as well as expansion of the progenitor has changed our fundamental understanding of lymphocyte biology. The antigen receptor can no longer be modeled as a digital on/off switch. Rather, the context in which the antigen is presented as well as the differentiation/activation state of the responding lymphocyte determines the lymphocyte's functional response.

Clonal deletion in thymus-derived lymphocytes (T cells)

An important distinction between T cells and B cells is that T cells can only recognize cell-bound (antigen-presenting cell, APC) antigenic peptides in the context of major histocompatibility complex (MHC) proteins. T cells are involved in surveillance of the peptides bound to MHC molecules in their environment from the earliest period of their development.

Thymus

The primary site for development of T cells is in the thymus. The process begins *in utero* as T cell progenitors migrate from their mesenchymal origin in the yolk sac and fetal liver and continues to a lesser extent after birth with progenitors from the bone marrow. These cells migrate to the thymus and begin to rearrange the genes encoding the heterodimeric T cell receptor (TCR). From this point forward the cells can be selected for complete maturation and export to the peripheral lymphoid organs (lymph nodes and spleen) or they are clonally deleted either because they fail to produce a functional TCR or because their TCR would be self-reactive in a functional, mature lymphocyte and cause autoimmune disease.

One reason T cells may fail to reach full maturity is because they are unable to complete the random rearrangement of the TCR genes. A second reason is that they successfully rearrange their genes and produce a functional TCR on the cell surface, but that protein with its CD4 or CD8 coreceptors does not recognize environmental MHC-peptide complexes sufficiently for completion of maturation. In a sense this failure of clones to be selected for further maturation is because they do not produce TCRs of sufficient affinity to be useful (Figure 2). The molecular basis of this arrested differentiation and subsequent cell death is not well understood, but is often referred to as deletion by 'neglect'. It is clear that the expression of anti-apoptotic proteins such as Bcl-2 in these cells can prolong their life, but does not ultimately rescue them for further differentiation.

Production of rearranged TCR gene products that alone, or in association with the CD4 and CD8 coreceptors, react strongly with MHC-peptide complexes results in the rapid death of the T cell progenitor (Figure 3). The death (active deletion) of these cells takes place at the double positive (CD4⁺CD8⁺) stage of T cell development, shortly after expression of a functional TCR. There appear to be no special APC requirements to induce deletion, but rather deletion is a function of peptide density on the APC and the affinity of the TCR for the MHC-peptide complex. Deletion can take place on any appropriate MHC⁺ cell in the thymus (MHC class I to delete CD8 cells and MHC class II to delete CD4 cells) but is generally thought to occur at the corticomedullary junction.

Figure 1 Depending on the activation state of the lymphocyte and the APC, antigen receptor engagement can result in either the selection and expansion of the clone or the death of the lymphocyte.

The molecular details of active deletion are incompletely understood. Evidence suggests that the time the TCR remains bound (k_{off}) to the MHC–peptide complex is the most important kinetic parameter determining the functional outcome. There is evidence from T cell hybridomas and from transgenic mice that *nur77*, an orphan member of the nuclear hormone receptor superfamily, may be involved in clonal deletion. However, animals with a null mutation in the gene for *nur77* demonstrate normal T cell development and function. Thus, *nur77*'s signaling function may be redundant. Some other member of the superfamily may be primarily involved and *nur77*'s physiological involvement is secondary to other pathways leading to T cell progenitor death.

Mature T cells

Antigen-stimulated death of mature T cells was not

Figure 2 The 'strength' of the interaction, determined by MHC–peptide density and TCR affinity, determines whether the developing thymocyte is clonally deleted or allowed to mature.

recognized until the early 1990s. Shortly thereafter, it was recognized that the process was defective in two mouse mutant strains associated with lymphoproliferative disease and autoimmunity (*lpr* and *gld*). At the same time, Nagata and colleagues determined that the molecular bases for the mutations are in a receptor–ligand pair. The *lpr* mutation functionally eliminates the expression of Fas (CD95/Apo-1) and the *gld* mutation is an inactivating, point mutation in Fas ligand (FasL) (Figure 4). The Fas (Apo-1) protein had previously been identified as a member of the tumor necrosis factor receptor (TNFR) family of proteins and produced apoptosis in sensitive cells when stimulated with agonist antibodies. The recognition of the importance of Fas in the animal models has led to the discovery that defective Fas expression is associated with lymphoproliferative disease and autoimmunity in some human patients.

Fas ligand is a member of the TNF family of proteins that act as membrane-bound or soluble homotrimers to aggregate their receptors into functional signaling units. Yeast two-hybrid analyses have revealed that both Fas and TNFR signal through a series of protein–protein interaction ('death') domains that result in the activation of a unique series of proteases cascading into 'programmed' cell death or apoptosis.

T cells from animals carrying the *lpr* mutation are defective both in culture and *in vivo* in dying in response to chronic exposure to high-dose antigen. It appears that Fas does not regulate most acute responses, but rather is important in limiting the expansion of lymphocyte populations to high doses and/or chronic exposure to antigen. This can be important both in limiting autoimmunity and in limiting the long-term response to immunogenic tumors. There is recent data that the related TNF system also

Figure 3 At various stages in T cell development, TCR stimulation or lack of stimulation results in death of those progenitors. Deletion can take place in the thymus by 'neglect' or by active deletion and in the periphery deletion can occur depending on the strength of the TCR/MHC-peptide interaction and on signals from costimulators.

plays an important role in the process of culture and *in vivo*. However, unlike animals with defective Fas or Fas ligand expression, the TNF role in lymphoproliferative disease or autoimmunity is not apparent when there are defects in TNF or its receptors alone, but rather appears to exacerbate the disease in animals with defective Fas or Fas ligand. It is likely that other members of this family will be identified that also contribute to lymphocyte hemostasis.

Fas is expressed at low levels on naive T cells and both its expression and sensitivity to signaling are increased after activation. In contrast, Fas ligand is transiently expressed upon TCR stimulation. The expressed ligand can act as a membrane-bound molecule to kill other cells (murder) or be released from the surface by metalloproteases as functional trimer. This soluble form of Fas ligand is important for the autocrine death (suicide) of the stimulated cell. There appear to be significant species differences in the stability of the soluble trimer. In addition, there appear to be soluble forms of Fas released from cells that neutralize the soluble Fas ligand. Thus under physiological conditions, soluble Fas ligand has a short functional range. Fas and Fas ligand do not

Figure 4 Chronic stimulation of the BCR creates an anergized B cell that increases Fas expression when stimulated by T cell CD40 ligand. It then dies in response to Fas stimulation by T cell Fas ligand. (Adapted from Rathmell *et al.*, 1996.)

appear to play a significant role in clonal deletion of thymic T cells.

Clonal deletion in antibody-producing B cells

Deletion of self-reactive clones of B cells is also an important part of antibody repertoire development. Like T cells, each clone of B cells produces a unique, antigen-specific membrane receptor. For B cells this is a membrane-bound form (BCR, B cell receptor) of the antibody produced and secreted by that cell. The BCR arises by alternative splicing of the antibody mRNA to include a membrane anchoring domain. Like the TCR, the BCR is associated with other proteins involved in transmitting signals into the cell upon stimulation. Unlike the TCR, the BCR binds protein, nucleic acids, carbohydrate and lipid sequences (antigenic determinants) independently of their association with MHC proteins. Thus B cells can be stimulated by both cell-bound and soluble antigens.

Progenitors for B cells develop from mesenchymal tissue in the yolk sac and fetal liver like T cell progenitors. However, there is a nearly continuous influx of new B cell progenitors for most of the life-

time of the animal, in contrast to T cells progenitor production that is largely restricted to embryonic and neonatal life. In avian species the B cell progenitors develop in the bursa of Fabricius (they were first discovered here and thus the term B cell), an appendix-like evagination of the avian gut. The bone marrow is the major source of B cell progenitors in other vertebrate adults. During B cell maturation there are several checkpoints where the developing clone can die either as a result of a negative signal from the BCR or from the lack of a positive signal from either the BCR or its environment (in this case a helper T cell).

Deletion of B cell clones prior to germinal center formation

Much of our understanding of the checkpoints in B cell development resulting in deletion has come from the analysis of BCR transgenic mice (mice carrying genes for a specific, rearranged BCR inserted into their genome and therefore expressed in virtually all developing B cells) by the laboratories of Goodnow, Weigart and Nemanzee. BCR transgenic animals were crossed to animals carrying their antigen as a transgene in various compartments and levels of expression. Antigenic determinants present as highly expressed membrane components cause the apoptotic death of the earliest progenitor with a functional BCR. This process is analogous to clonal deletion of autoreactive T cells in the thymus but the molecular basis is currently unknown.

Clones of developing B cells that fail to successfully rearrange their BCR or whose BCR is not stimulated within 1–3 days after export to the primary lymphoid organs (lymph node and spleen) also die. Death of the newly developed B cell also occurs if it is stimulated by antigen, but does not promptly receive a helper signal (helper T cell cytokines or surface molecules such as CD40 ligand). Cells that are chronically stimulated by soluble antigen (e.g. B cells that react to serum proteins) from their earliest stages of development become anergic. That is restimulation by antigen and helper cells fails to produce normal proliferation and maturation into antibody-secreting cells. These anergized but potentially autoreactive cells are exported to the primary lymphoid organs, but are eliminated in two ways: 1) they remain in the periarteriolar zones and do not compete with normal B cells for space in follicles and germinal centers where continued expansion and maturation occurs; or 2) they are killed by activated T cells.

The lysis of the anergic B cells by T cells is dependent on the Fas/Fas ligand pathway and in *lpr* animals lacking Fas, autoreactive B cells accumulate in

the T cell-rich, periarteriolar sheath. Adoptive transfer studies have indicated that elimination of these anergic B cells requires functional Fas on the B cell and functional Fas ligand on the T cell. In addition, it requires cooperation with other members of the TNF family. In this case CD40 on the B cell and CD40 ligand on the T cell. Stimulation of CD40 on the B cell induces the expression of Fas on that cell and stimulation of B cell Fas by Fas ligand on the T cell causes the death of that anergic B cell (Figure 4). Interestingly, the same sequence of events with normal B cells after acute antigen stimulation is required for B cell proliferation and maturation. Thus the activation state of the B cell (chronic versus acute) determines the functional outcome (death versus expansion and maturation) of the T/B cell interaction.

Deletion of B cells after primary activation

Thus far we have discussed elimination of B cells during the maturation of progenitors. However, mature B cells, unlike mature T cells, can undergo somatic mutation of their BCR after antigenic stimulation. This property allows affinity maturation of the response in germinal centers to produce higher affinity antibodies for a given challenge, but also creates a new risk of autoantibody development. One mechanism for solving the problem is analogous to the costimulator strategy in T cells. In this case the 'costimulator' CD19 dramatically lowers the number of BCRs needed to be occupied for maximal proliferation by allowing synergistic signaling between the complement receptor CD21 and the BCR. Cells stimulated by antigen in the context of complement (e.g. on the surface of a bacterium) or complement on the surface of a specialized antigen-presenting cell (follicular dendritic cell, FDS) do not undergo apoptosis. The FDC can also provide a similar function through CD23 on its surface. Stimulation of the germinal center B cell (centrocyte) by antigen in the absence of complement or CD23 stimulation results in deletion of those clones. This type of clonal deletion of mature B cells is independent of the Fas system. Rather, complement or FDC stimulation of the B cell regulates the expression of antiapoptotic molecules such as Bcl-2 and deletion of the cells not receiving signals from both the BCR and the costimulator are deleted by a pathway more analogous to the 'neglect' pathway of thymocytes.

Summary

Regulated survival of clonal progenitors is a primary mechanism of determining the lymphoid repertoire. Clones that are unwanted either because they do not express useful antigen receptors or express receptors

that would cause autoimmune disease are deleted through a death process. There appear to be two general strategies to eliminate these cells. In some instances (e.g. through Fas and Fas ligand) a clear receptor–ligand interaction actively initiates a death response. In other circumstances such as in the thymus or in germinal center B cells it appears that death is a ‘default’ step in the differentiation pathway that occurs unless there is active intervention by signals from other cell surface molecules that rescue them from death by regulating the expression of anti-apoptotic molecules like Bcl-2.

CLONAL SELECTION

Norman R Klinman, The Scripps Research Institute, California, USA

By the mid-1950s numerous theories had been proposed to account for the remarkable capacity of the immune system to respond specifically to the myriad of foreign antigenic determinants. One group of theories, championed by Alexander, Mudd, Haurowitz, Pauling and Karush, relied on the entry of antigen into antibody-forming cells to serve as a template for the synthesis of complementary antibodies, and, as such, were considered ‘instructional’. A novel ‘natural selection theory’, put forward by Jerne in 1955, suggested that all potential antibodies pre-existed as ‘natural antibodies’ and

appropriate cells, internalizing antigen complexed to a given antibody, would duplicate the internalized antibody. In 1957, Talmage suggested that cells might express their potential antibody as a cell surface receptor, and in 1958 Macfarlane Burnet fully elaborated the ‘clonal selection theory’. This theory, like Jerne’s theory, proposed that appropriate antibodies pre-existed in the absence of antigen ‘instruction’ but that the diverse array of antibodies was the product of multiple cell clones, each capable of expressing a single antibody product. The major tenets of the hypothesis were as follows (all

quotations excerpted from Burnet (1959), see Further reading):

1. 'in the animal there exist clones of mesenchymal cells each carrying immunologically reactive sites corresponding in appropriate complementary fashion to one (or possibly a small number of) potential antigenic determinants'.
2. These clones provide 'a population of cells which, when an appropriate stage of development has been reached, are capable of producing the population of globulin molecules which collectively provide the normal antibodies'.
3. In order that antigen-antibody complexes localize to 'cells, which are genetically determined to produce the corresponding type of antibody molecule - it would simplify matters a great deal if the antigen were in a position to react with natural antibody or a pattern equivalent thereto on the surface of the cell which produced it'.
4. 'When an antigen is introduced it will make contact with a cell of the corresponding clone, presumably a lymphocyte, and by so doing stimulate it to produce in one way or another more globulin molecules of the cell's characteristic type.'
5. That this 'stimulation initiates proliferation'.
6. 'that active sites on cell surface or globulin molecule can be modified to a wider reactivity by somatic mutation, provides the chief agent to allow change in antibody character as immunization proceeds.'
7. 'Self-not-self recognition means simply that all those clones which would recognize (that is, produce antibody against) a self-component have been eliminated in embryonic life. All the rest are retained.'
8. The secondary response is accounted for thus: 'on the simplest form of the hypothesis - the primary stimulus finds only a few examples of the appropriate clones; by the time of the secondary stimulus, many more individuals of the selected clones are accessible'.

Over the past 30 years each of these postulates has to a considerable extent been validated by experimental observation. Although other elements of Burnet's thesis are not as prescient as the above, it should be noted that prior to 1960 neither the molecular basis for antibody formation nor the T cell-B cell dichotomy and cell-cell collaboration were understood.

Unipotentiality of lymphoid cells

The most fundamental tenet of the clonal selection hypothesis, and that which distinguished it from all others, was 'the *existence of multiple clones of globulin-producing cells*, each responsible for one genetically determined type of antibody globulin'. Indeed, in discussing the implication of the theory, Burnet stated 'the clonal selection hypothesis would be completely validated if it could be shown that single cells from a non-immune animal gave rise to clones, each cell of which under proper physiological conditions contained, or could liberate, antibody-type globulin of a single pattern or at most of a uniform small range of patterns'. Early efforts to test this postulate were hardly supportive. Attardi, Horabita, Lennox and Cohn concluded, from single-cell studies of phage-specific antibodies, that single cells were multipotential. Studies from a variety of laboratories, including those of Cunningham, Liacoupoulos, Hiramoto and Sercarz, appeared to demonstrate multiple antibodies per single cell. Additionally, Burnet's own experiments, using a tissue reactivity test devised by Simonsen, were incompatible with a highly diverse repertoire of unipotential cells. However, in retrospect, each of these anomalous findings has been attributable to experimental artifact, the capacity of certain antibodies to bind numerous antigens (multispecificity), or, as in the case of the Simonsen assay, an inordinately high frequency of T cell responses to any given major histocompatibility complex (MHC) alloantigen.

In addition, the numerous examples of the homogeneity of immunoglobulins produced by multiple myeloma cells and the existence of restricted antibody responses to certain antigens, such as Krause's demonstration of restricted antibodies in rabbits responding to A-carbohydrate, implied that the product of single antibody-forming cell clones was homogeneous. A similar conclusion was drawn from findings of numerous laboratories, including those of Nossal, Mäkelä and Biozzi, that single cells bound only one antigen. Using the splenic focus assay, where single antigen-specific precursor cells were isolated in cultures of splenic fragments, Klinman demonstrated, in 1969, the homogeneity of the antibody product of the clonal progeny of a single stimulated precursor cell (Figure 1). These studies demonstrated, by the homogeneity of antigen binding as well as heavy (H) and light (L) chain recombination analyses, that the product of antibody-forming cell clones was homogeneous and displayed binding characteristics that, in composite, could account for the affinity and heterogeneity characteristics of

Figure 1 Hapten binding curves constructed from equilibrium dialysis at 7°C with a) antibody from two antibody forming cell clones (foci) generated in splenic fragments, focus No. 1434 (●) and focus No. 2560 (■); and b) pooled antibody from the clonal progeny of numerous secondary B cells (○). r represents the moles of α , N-(³H)-acetyl- δ -DNP lysine bound per mole of antibody at the equilibrium free hapten concentration, c . Antibody concentrations were determined at each point by radioimmunoassay and points represent duplicate samples which agreed to within 5%.

serum antibodies. Although these particular studies used B cells from previously immunized mice, subsequent studies extended these findings to B cells from nonimmune mice, thus fulfilling Burnet's requirements. The only exception to the homogeneity of the antibody produced by single clones was the production of multiple isotypes by most clones; however, Gearhart and Klinman demonstrated that antibodies of different isotypes generated from the same clone shared variable regions. In recent years, the molecular mechanisms that account for the sorting of unique specificities to individual lymphocytes have become well documented and are discussed elsewhere in this volume.

Immunoglobulin receptor on B cells

Essential to 'clonal selection' is the availability of a mechanism to focus the antigen to the appropriate B cells and, in so doing, enable the stimulation of those B cells. In 1967 Mitchison and his coworkers indirectly demonstrated that the fine specificity of antibody produced by B cells could be influenced by selectively stimulating these cells with a cross-reactive hapten. This indirect demonstration of a correlation between the B cell's surface receptor and secreted antibody product was later extended by Klinman, who demonstrated that clonal precursors whose potential antibody product was of high affinity could be selectively stimulated with low antigen

concentrations. That B cells bore surface immunoglobulin was demonstrated by numerous investigators including Naor, Sulitzeanu, Wigzell, Vitetta, Uhr and Marchalonis, and the mobility of these receptors on the cell surface was shown by Raff and Taylor. However, the identity between the B cell's potential antibody product and its surface immunoglobulin receptor awaited the demonstration by Köhler and Cosenza that they shared idiotype.

Tolerance and memory

In part, the clonal selection hypothesis was necessitated by the need to account for two fundamental hallmarks of the immune response: the capacity to respond to nonself or foreign antigens while not responding to self antigens; and the long-term retention of the capacity to mount accelerated and vigorous responses to previously encountered antigens. As anticipated by the theory, numerous studies have demonstrated the inactivation of developing B and T cells by antigens present in their environment, thus validating negative clonal selection as the basis for self tolerance. Although most B cells in an unimmunized animal have the capacity only to generate antibody-forming cell clones and not memory B cells, Linton, Decker and Klinman have identified a subpopulation of precursor cells that do give rise to memory B cells and that fulfill, in detail, Burnet's predictions: 1) 'that a first contact with antigen sets some sort of tooling-up process in train, while secondary contact is needed to evoke actual antibody liberation into the circulation'; and 2) that 'the combination of frequent minor mutation and a highly effective selective process would rapidly improve the accuracy of the complementary relationship to new antigenic determinations'. The process of somatic mutation and antigen selection of these mutations has been described by numerous investigators including Tonegawa, Weigert, Geffer, Rajewsky, Berek and Milstein.

Conclusion

Since its first elaboration, the clonal selection hypothesis has served as the take-off point for experiments, not only to test the theory itself, but also to extend our knowledge of the mechanism of immune responsiveness. While many of the speculations with which Burnet decorated this theory have not stood the test of time, the fundamental aspects of the theory remain and constitute the foundation of our current understanding of the immune response.

CLOSTRIDIUM, INFECTION AND IMMUNITY

Charalabos Pothoulakis, Beth Israel Deaconess Medical Center, Division of Gastroenterology, Harvard Medical School, Cambridge, Massachusetts, USA

Characteristics of the organisms and their antigens

The clostridia are spore-forming rod-shaped gram-positive bacteria that usually grow under anaerobic conditions. An important characteristic of these microorganisms is their ability to survive in high numbers for long periods of time in feces and soil, an ability related to the formation of spores which can be very resistant to temperature and pH extremes. Clostridia are potent pathogens in animals and humans because of their ability to release various exotoxins. Furthermore, many clostridia species release more than one toxin and each toxin is immunologically distinct. For example, eight types of *Clostridium botulinum* and five types of *Clostridium perfringens* have been identified and each type elaborates different toxins. Many similarities exist among clostridial toxins. Amino acid homology and immunologic cross-reactivity exist between *C. difficile* toxins and *C. sordellii* lethal toxins and between tetanus toxins and botulinum B toxin, and these toxins have similar mechanisms of action. In addition, many clostridia produce a variety of enzymes, including collagenases, proteinases, deoxyribonucleases, and neuraminidases, which compromise the host and increase the pathogenicity of these microorganisms.

Although most of the clostridia toxins are large protein exotoxins with distinct biochemical proper-

ties and immunological characteristics, classification of these toxins based on their pharmacologic properties and cellular targets is far from complete. For the purpose of this review clostridia toxins will be categorized according to the diseases they produce into four groups: 1) neurotoxins, represented primarily by *C. tetani* and *C. botulinum* which are associated with tetanus and botulism in humans; 2) enterotoxins, represented by *C. perfringens* enterotoxin produced by some strains of *C. perfringens* type A which mediate acute food poisoning, *C. perfringens* ϵ and ι toxins causing enterotoxemia in sheep, calves, lambs and guinea pigs, and *C. sordellii* hemorrhagic toxin which is associated with diarrhea in cattle and sheep; 3) histotoxins or cytolytic toxins, represented by some of the *C. perfringens* toxins that are associated with gas gangrene and anaerobic cellulitis, and *C. sordellii* lethal toxin (LT), one of the causes of gas gangrene; and 4) cytoskeleton-altering toxins, represented by *C. difficile* toxins A and B, that mediate antibiotic-associated colitis and diarrhea following antibiotic intake in animals and humans, and *C. botulinum* C2 toxin. All cytoskeleton-altering toxins disrupt filamentous (F) actin in target cells. It should be emphasized, however, that many of these toxins have several other biological activities other than the ones listed above. For example, toxin A of *C. difficile* is also a potent enterotoxin that induces fluid secretion when injected into rabbit and rat intestinal loops.

An interesting topic of pathogenicity associated with clostridial toxins is the molecular mechanism by which these toxins modify properties of cellular proteins and, by altering their function, cause human disease (Table 1). Toxins are enzymes which can biochemically modify specific molecules on the plasma membrane or cytosol of target cells. Some of the *C. perfringens* toxins are very good examples of toxins which act on plasma membranes of cells. *C. perfringens* α toxin, a phospholipase C or lecithinase, cleaves lecithin in cell membranes into diglyceride and phosphorylcholine as well as hydrolyzes cephalin and sphingomyelin. *C. perfringens* κ toxin is a collagenase, whereas the μ toxin is a hyaluronidase.

A major breakthrough in our understanding of the pathogenesis of tetanus and botulism has been the recent identification of the molecular mechanism by which *C. tetanus* and *C. botulinum* B toxins cause paralysis. Botulinum neurotoxins act on peripheral motor nerves to block acetylcholine release at neuromuscular junctions, thereby causing muscle paralysis (flaccid paralysis). On the other hand tetanus neurotoxin acts on the central nervous system by blocking neurotransmitter release from inhibitory neurons causing muscle spasms (spastic paralysis). Although these two diseases have different clinical symptoms it is now known that botulinum B and tetanus neurotoxins have identical mechanism in intoxicating

nerve cells. Both toxins are zinc endopeptidases that require a zinc atom for their activity and both have a similar protein structure with a receptor binding B domain and a catalytic A domain. The mechanism of action of these toxins initially involves binding to cell surface receptors and internalization into the cytosol. Once into the cell the toxins are then cleaved by proteases into active fragments which possess catalytic action. The cellular target of botulinum B and tetanus toxin is synaptobrevin, a membrane protein which is important in neurotransmitter release and associated with small synaptic vesicles. The active forms of botulinum and tetanus toxin inactivate synaptobrevin by cleaving it at a specific peptide site.

Another important recent discovery in the field of clostridial toxins is the cellular mode of action of large clostridial toxins including *C. difficile* toxins A and B, and *C. sordellii* and *C. novii* toxins. The common characteristic of these toxins is their large molecular weight (>250 kDa), amino acid similarity, absence of subunits, and their similar cytopathogenic (rounding) effect on cultured cells. These toxins exert their cytopathogenic effect by modifying specific small GTP-binding proteins of the Ras superfamily that regulate cellular actin. Studies with *C. difficile* toxins showed that these toxins bind to specific cell receptors and are then internalized into the cytosol

Table 1 Mechanisms of some clostridial toxins

Organism	Disease	Major lethal toxins	Mechanism of toxicity
<i>C. perfringens</i> type A	Gas gangrene	α toxin	Cytotoxic, calcium-dependent phospholipase C
	Food poisoning	Enterotoxin	Changes permeability of cells.
<i>C. perfringens</i> type C	Gas gangrene	α toxin	Calcium-dependent phospholipase
	Enteritis necroticans	β toxin	Cytotoxin, pore-forming?

via coated pits. Once into the cytosol these toxins monoglucosylate the small GTP-binding proteins Rho, Rac and Cdc-42 at position Thr37. As a result, these small GTP-binding proteins are unable to regulate actin polymerization thus leading to actin filament breakdown and cell rounding. *C. sordellii* lethal toxin, which also rounds up cells and causes disruption of actin fibers, also glucosylates the small GTP-binding proteins Ras, Rap and Rac, that regulate actin filament formation. These recent discoveries on the molecular mechanism of clostridial toxins not only increase our understanding of their cellular actions, but may also help to design rational prevention or treatment of diseases associated with these toxins.

Evasive strategies by the organism

Clostridia have devised many ways to enter the host and cause disease. In the case of gas gangrene and wound infections *C. perfringens* enters the host through traumatic or surgical wound often taking advantage of poor blood supply in the wound area. Once clostridia grow they release their toxins and cause disease. In *C. difficile*-associated colitis the bacteria multiply when the normal bowel flora is disrupted by antibiotics. *C. difficile* then releases its toxins which target intestinal epithelial cells and cause diarrhea and colonic inflammation. In the case of botulism, however, the organism does not grow in the host but the disease is caused by ingestion of *C. botulinum* toxins present in contaminated food.

Immune responses of the host and vaccines

For most clostridial-mediated diseases, there is no immunity following the experience of the first episode. The reasons for absence of prophylaxis following exposure of patients to clostridia and their toxins is not clear but could involve the small

amount of toxins required to produce disease, which may be inadequate to produce an immunogenic response. Despite the absence of systemic immunity following disease, toxoid immunization against tetanus provides immunity for up to 5 years. Passive immunization with tetanus immunoglobulin is also of great value in suspected cases. An antitoxin antibody has also been available for laboratory workers, and intravenous treatment with gamma globulin preparations containing a high-titer antibody to *C. difficile* toxin was effective in treating patients with relapsing *C. difficile* diarrhea.

CLOTTING SYSTEM

Arthur S Brecher, Department of Chemistry, Bowling Green State University, Bowling Green, Ohio, USA

The clotting system consists of a mixture of components including cells, fragments thereof, zymogens, their activation products and naturally occurring inhibitors, adhesive and structural proteins, phospholipids, lipids, cyclic and noncyclic nucleotides,

hormones and inorganic cations, all of which are normally maintained in a state conducive to blood flow. Upon damage to the vascular wall with disruption of the monocellular layer of endothelial cells, exposing the subendothelial layer, and also permit-

ting bleeding, a series of events is initiated designed to produce clot formation. These homeostatic reactions lead to the generation of the primary platelet plug, followed by a clot principally containing cross-linked fibrin (secondary hemostasis). Subsequently, the blood vessel is repaired and the clot is dissolved by a mechanism which includes fibrinolysis.

Local vasoconstriction

A number of physiologically derived compounds appear to induce vasoconstriction of a transient nature at the site of vascular injury. These include participation of endothelin, a very potent vasoconstrictor which is synthesized by endothelial cells, thromboxane A_2 (TXA $_2$), serotonin and the α -adrenergic system. Thrombin, interleukin 1 (IL-1), transforming growth factor β (TGF β), angiotensin II and epinephrine promote the expression of endothelin mRNA, whereas shear stress, atrial natriuretic peptides (ANP) and brain natriuretic peptides negatively modulate its expression. Endothelial-derived relaxing factor (EDRF), an inhibitor of platelet function, inhibits the release of endothelin. The lung clears endothelin from the circulation. Angiotensin II, also a vasoconstrictor, is synthesized locally, as renin and angiotensinogen are generated within the endothelial cell (EC), and angiotensin-converting enzyme (ACE) is found on the surface of the EC membrane. As a counterbalance to constriction, ECs secrete such vasodilators as adenosine, prostacyclin and EDRF. Nitric oxide (NO) exhibits similar effects as EDRF. However, S-nitrosocysteine appears to behave more akin to EDRF. The final identity of EDRF, is, as yet, unresolved. The ECs also can degrade serotonin.

Platelet components and function

Disk-shaped platelets circulate in the blood, being quite unreactive with the intact vascular wall. Upon injury to the vascular wall, however, components from the platelets, ECs and damaged subendothelial cells (SECs) (SEC matrix), other vascular tissue constituents and circulating plasma components contribute to the formation of a primary platelet plug. The sequence of reactions in response to injury is as follows: initial activation and adhesion of platelets to the damaged SECs, contributing to activation of circulating platelets, and aggregation of platelets to one another at the site of injury, followed by stabilization of the platelet plug by extensive cross-linking of polymeric fibrin molecules. Platelet membrane proteins include numerous receptors for adhesion proteins such as collagen, fibrinogen, fibronectin, von Willebrand factor (vWF), thrombin receptor, and

others. Dense granule constituents in platelets include ATP, ADP, Ca $^{2+}$ and serotonin, while α granule components of platelets include platelet factor 4 (PF4), β -thromboglobulins, fibrinogen, vWF, fibronectin, thrombospondin, coagulation factors V, XI and protein S (PS), α_2 -antiplasmin (α_2 -AP) and plasminogen activator inhibitor 1 (PAI-1). Cytoplasmic proteins which are secreted by platelets are represented by protease nexin I, protease nexin II, tissue factor pathway inhibitor (TFPI), factor XIII, α_1 -antitrypsin (α_1 -AT), C1-inhibitor, α_2 -macroglobulin (α_2 -MG), high molecular kininogen (HMWK) and II-I β). Endothelial cells release prostacyclin (PGI $_2$), an inhibitor of platelet aggregation, as well as platelet activating factor (PAF) and vWF, which contribute to platelet adhesion, in addition to fibrinolytic components, tissue plasminogen activator (t-PA) and PAI-1. The mechanisms for release of these compounds is not yet understood. Thrombomodulin (TM), tissue factor (TF), ACE and binding sites for factors Va, Xa, and XIa are observed on EC membrane surfaces. However, TF is expressed only upon injury to tissue. The subendothelial tissue damage exposes such adhesive proteins as collagen (types IV, V and VI), vWF, fibrinogen and vitronectin, while the damaged media exposes collagen (types I and III), and damaged adventitia exposes collagen and TF.

Flow rate of blood affects adhesion of platelets to the damaged SECs. In areas of low blood flow, collagen and fibronectin play a greater role as adhesive proteins linking the platelets to the SEC. With higher flow areas, however, vWF appears to play a more significant role as an adhesive protein. Upon vascular injury, multimers of circulating vWF bind to platelet receptor glycoprotein GPIb/IX. Subsequently, GPIIb/IIIa receptors are activated. The complex then binds to exposed collagen and fibronectin on the SEC matrix. Additionally, newly exposed SEC matrix-bound vWF binds to circulating platelets. GPIa/IIa receptors on the platelet surface also permit direct binding of platelets to the exposed collagen from the SEC matrix. Additionally, collagen binds fibrinogen, fibronectin and vWF, thereby stimulating further binding with GPIIb/IIIa, GPIc/II and GPIb/IX receptors on the platelet surface.

The activation of platelets is stimulated by strong and weak agonists. Thrombin, which may be locally generated at the site of injury, and collagen have been identified as strong agonists while ADP, epinephrine, TXA $_2$, serotonin, PAF and vasopressin (Vp) have been relegated as weaker agonists. The consequences of platelet activation are: alteration of platelet shape from discoid to globular, with pseudopods; increased cytosolic Ca $^{2+}$; alteration of the GPIIb/IIIa receptor to a high-affinity receptor in

order to effectively bind vWF and/or fibrinogen for adhesion/aggregation; biosynthesis of TXA₂, a vasoconstrictor, and other eicosanoids from arachidonic acid (AA); phosphorylation of platelet proteins; induction of platelet coagulation activity; release of dense granule constituents (ADP, ATP, Ca²⁺, serotonin, pyrophosphate); release of α granule constituents (platelet-specific proteins such as PF4, which interacts with heparin and lowers its anticoagulant activity; β -thromboglobulin, and adhesive glycoproteins such as fibrinogen, vWF, and fibronectin); release of lysosomal constituents, expression to the cell surface of dense and α granule membrane proteins, factors V and XI and PS; inhibitors of fibrinolysis (α_2 -AP, PAI-1); platelet-derived growth factor (PDGF).

Platelet activation involves the mobilization of two enzyme systems in response to agonists. Phospholipase A₂ (PLA₂) and phospholipase C (PLC) act upon platelet membrane phospholipid (PL) substrates. PLA₂ cleaves AA from phospholipids. (Linoleic acid may also serve as a metabolic precursor to AA in mammals.) Upon subsequent successive action on AA by a cyclo-oxygenase and a peroxidase, prostaglandin H₂ (PGH₂) is formed. PGH₂ serves as the precursor to TXA₂ (mediated by TXA₂ synthase) and PGI₂ (mediated by PGI₂ synthase). The EC is a major source of TXA₂. TXA₂ then alters platelet shape and stimulates platelet aggregation. It also promotes the platelet secretion and expression of the fibrinogen receptor. (PGI₂ inhibits platelet aggregation.) The alternative activation pathway involves hydrolysis of membrane PL by PLC to produce diacylglycerol (DAG), inositol triphosphate (IP₃) and some AA. The AA is metabolized by the cyclo-oxygenase and peroxidase in the above described manner. In addition, IP₃ promotes an increase in cytosolic Ca²⁺, which stimulates an alteration in platelet shape, platelet secretion and fibrinogen expression. DAG affects identical changes in platelet shape and function.

A number of factors act counter to the activation of platelets. These include PGI₂, EDRF, NO and ecto-ADPases, derived from ECs which degrade the platelet activator ADP into adenosine, a platelet function inhibitor. Furthermore, substances which negatively modulate the activity of thrombin, the strong agonist for platelet activation, contribute to antiplatelet activation controls. These include antithrombin III (AT III), α_2 -MG, heparin cofactor II (HC II), and activated protein C inhibitor I (APCI). Additionally, 13-hydroxyoctadecadienoic acid (13-HODE), produced in the ECs, inhibits adhesion and aggregation of platelets and TXA₂ synthesis, and promotes the synthesis of PGI₂.

Subsequent to platelet adhesion and activation, additional circulating platelets aggregate to the platelet monolayer. Aggregation involves the participation of fibrinogen which binds to the GPIIb/IIIa receptor site of the platelet membranes and forms a bridge to another platelet, thereby expanding the platelet plug. There are two binding sites for the GPIIb/IIIa receptor on each fibrinogen molecule.

Secretion of the platelet granule components as well as cytosolic proteins (protease nexin I and II, TFPI, factor XIII, α_1 -AT, C1-inhibitor, HMWK, α_2 -MG, vascular permeability factor and IL-1 β) adds components for positively or negatively affecting coagulation in the blood vessel at the site of vascular injury.

As part of the activation process, a rearrangement of phospholipids occurs whereby phosphatidylserine and phosphatidylinositol position themselves from the inner surface of the platelet membrane to the outer surface as a means of presenting a negative charge to coagulation factors for binding purposes.

Contraction of the clot and secretion of granule proteins are believed to incorporate the use of the contractile protein, actinomyosin.

Coagulation and its modulation

A veritable cascade of limited proteolytic reactions are encompassed in the coagulation process. A series of inactive proteins, namely, zymogens, are sequentially activated by limited proteolysis, culminating

ultimately in the formation of the stable, insoluble fibrin clot. Many of the activated zymogens are serine proteases, descended from the same evolutionary tree as the digestive enzymes, trypsin, chymotrypsin and elastase. They contain the catalytic triad consisting of histidine, aspartic acid and serine. These include kallikrein, thrombin, factors VIIa, IXa, Xa, XIa and XIIa from the coagulation cascade and plasmin, t-PA, and urinary-plasminogen activator (u-PA) from the fibrinolytic enzyme system. This hemostatic process was historically conceived to meld an *intrinsic* pathway with an *extrinsic* pathway at a juncture resulting in the activation of factor X to factor Xa, whereupon a common pathway concluded with the formation of the fibrin clot. The clotting cascade including the *extrinsic* and the 'historic' *intrinsic* pathways, together with the fibrinolytic system for dissolution of the clot, is depicted in Figure 1. Activation of the historic *intrinsic* pathway could be accomplished upon contact of factor XII with a negatively charged surface to yield the activated factor XIIa. It was observed that factor XIIa could activate two zymogens, prekallikrein (PK) and factor XI, each in the presence of HMWK. Activation of PK yields the protease kallikrein (K). K, in turn, activates factor XII in the presence of HMWK to produce additional factor XIIa, a positive feedback step as the *intrinsic* cascade is initiated. (K activity is inhibited by α_1 -AT, α_2 -MG, C1-inhibitor and APCI.) The activation of factor XI by factor XIIa yields factor XIa. Factor XI is also activated by factors XIa and IIa (thrombin), the latter activation requiring heparin as a cofactor. The activation of factor XIa by thrombin is inhibited by fibrinogen. (Antithrombin III (AT III) and APCI inhibit the subsequent proteolytic activity of factor XIa).

All subsequent steps involving the *intrinsic* system factors occur on membrane surfaces such as the platelet membrane. Endothelial cell membranes also bind coagulation factors. PL is required, serving as the negatively charged surface. The localization of PL in the membrane permits the formation of ternary and quaternary complexes as necessary, for the accomplishment of the clotting steps. Factor XIa activates factor IX in the presence of Ca^{2+} . (AT III inhibits the proteolytic activity of factor IXa.) Factor IXa, in the presence of factor VIIIa and Ca^{2+} , activates factor X to factor Xa. The activation of factor VIIIa will be dealt with below. Factor Xa then activates prothrombin (factor II) to yield thrombin (factor IIa). This occurs with the mediation of factor Va in the presence of Ca^{2+} . Thrombin subsequently acts upon circulating or locally entrapped fibrinogen to generate the initial fibrin gel which is then cross-linked with the assistance of a transglutaminase, fac-

tor XIIIa, in the presence of Ca^{2+} . Fibrinogen is a protein containing six polypeptide chains, two $\text{A}\alpha$, two $\text{B}\beta$ and two γ chains, appropriately linked via disulfide bridges. Initial activation of fibrinogen by thrombin causes the release of fibrinopeptide A from the α chain in a relatively rapid reaction, permitting polymerization of the remaining protein. A rate-limiting cleavage of fibrinopeptide B from the $\text{B}\beta$ chain subsequently occurs. The resultant fibrin molecules may then be cross-linked longitudinally and transversely by factor XIIIa. Factor XIIIa is activated by thrombin from its inactive precursor, factor XIII, in the presence of Ca^{2+} . Factor XIIIa also functions in the presence of Ca^{2+} . The transglutaminase excises the amide groups of select glutamines in the carboxyl terminal region of γ chains and links the resultant glutamic acids with select ϵ -amino groups of lysines in the carboxyl terminal region of the γ chains. It also acts similarly with the α chains. Longitudinal cross-links are established with γ - γ as well as α - α chains, whereas transverse links are formed only with α - α chains. The resultant polymeric product is increasingly insoluble and more resistant to proteolysis. Factor XIIIa cross-links other localized proteins in addition to fibrin, such as fibronectin, thrombospondin, collagen, actin, vWF and α_2 -AP, in forming a tight mesh. Hence, components related to coagulation and fibrinolytic mechanisms may be effectively entrapped at the coagulation site. As will be discussed below in the fibrinolytic section, plasminogen is incorporated in the fibrin clot. Furthermore, t-PA binds to fibrin.

Factor Xa and thrombin have multiple roles in the clotting system. Thrombin activates the inactive factor XIII to the active factor XIIIa in the presence of Ca^{2+} . The initial fibrin gel appears to promote this step. In addition to activating factors XI and XIII, thrombin activates factor V to factor Va, factor VIII to factor VIIIa in the presence of Ca^{2+} , and the tissue factor-VII (TF-VII) complex to its active form, TF-VIIa.

TF is considered as part of the *extrinsic* blood clotting pathway (to be described shortly, after further discussions of factors Va, VIIIa, IIa and Xa). Factor Xa also catalyzes the activation of factor V, as does thrombin. The activation of factor VIII by thrombin is more complex. Factor VIII circulates in blood as a complex with vWF. In the process of activation of factor VIII by thrombin, vWF dissociates from the complex, thereby availing itself of the opportunity to complex with more circulating factor VIII. vWF stabilizes factor VIII, thereby prolonging its circulating half-life. Factor VIIIa can apparently be degraded to degradation products spontaneously. This degradation occurs at a reduced rate in the presence

of high concentrations of factor IXa. Factor Xa also activates factor VIII to factor VIIIa. The activation of factors Va and VIIIa by thrombin and factor Xa serve as additional examples of positive feedback.

Factors Va and VIIIa, which participate in the coagulation system as cofactors of factor Xa and IXa, respectively, are also subject to enzymic degradation. Both factors Va and VIIIa are degraded by a complex of activated protein C (APC) with protein S (PS), APC-PS. The formation of the APC-PS complex occurs on the membrane surface, as do all the reactions in the clotting cascade from the functioning of factor XIa to the activation of prothrombin. The series of reactions begins with the initial formation of a complex comprising thrombin, thrombomodulin (an EC membrane protein) and Ca^{2+} on the membrane. This complex catalyzes the transformation of protein C (PC) to APC. The APC interacts with PS to yield the APC-PS complex in which the APC contains the catalytic degradative potential to fragment factors Va and VIIIa. Under such circumstances, the catalytic functions of factors IXa and Xa are depressed, thereby reducing the generation of thrombin from prothrombin. Hence, thrombin can act not only as a positive modulator (positive feedback) in activating factors Va and VIIIa, but also as a negative modulator by initiating the formation of APC-PS which degrades factors Va and VIIIa, limiting thrombin production. An inhibitor of APC (APCI) has been identified which inhibits the formation of the APC-PS complex from its APC and PS components. It further inhibits the functioning of factor XIa. It therefore functions overall to promote clotting at the Va and VIIIa steps by 'lowering' their 'inactivation' rate. Its effect on factor XIa may be of questionable impact, as discussed below. Another protein, a plasma component, C4b-binding protein (C4b-BP), also negatively modulates the degradation of factors Va and VIIIa by forming a complex with PS, the PS-C4b-BP complex which competitively blocks the formation of the APC-PS complex.

Thrombin activity is inhibited by four naturally occurring proteins: antithrombin III (ATIII), α_2 -MG, HCII, and APCI. The APCI also inhibits factor Xa. ATIII, HCII and APCI are *serpins* (serine protease inhibitors). ATIII is a glycoprotein which is capable of forming a stable tetrahedral complex with thrombin thereby inactivating it. ATIII also inhibits factors IXa, Xa, XIa and XIIa. ATIII contains two domains for binding heparin. Both domains are rich in basic amino acids. Hence they readily bind to the negatively charged sulfate esters in heparin. They also bind to heparan sulfate, a proteoglycan which is synthesized by ECs and expressed to their surface. Hep-

arin is synthesized by mast cells and is detected in granules of these cells beneath endothelial tissue. When ATIII binds to heparin to form an ATIII-heparin complex, the conformation of the ATIII is presumably altered, significantly enhancing reaction with thrombin. Following formation of the ATIII-thrombin complex, heparin is released, thereby permitting it to react with free ATIII molecules. The heparan sulfate-ATIII complex is also a powerful inhibitor of thrombin. HCII inactivates thrombin. Its inactivation of thrombin can be accelerated 1000-fold by complexing with dermatan sulfate, a mucopolysaccharide component of the vascular wall.

As may be seen in Figure 1, factor Xa exerts multiple roles in coagulation, as does thrombin. It activates factors II, V and VIII, thereby promoting the clotting process. It also activates factors IX on a membrane surface, a positive feedback step, thereby stimulating its own activation from factor X, and is further involved in the activation of factor IX by activating the TF-VII complex of the *extrinsic* clotting system. Lastly, it is a component of a negative feedback system whereby it complexes with tissue factor pathway inhibitor (TFPI) to form the Xa-TFPI complex which inhibits factor Xa function as well as TF-VIIa function (Factor Xa is also inhibited by ATIII and by APCI.)

The significance of the contact system for the initial activation of blood clotting in the intrinsic clotting pathway has been questioned as a functional pathway *in vivo* as a deficiency in factor XII does not lead to a clotting abnormality. In addition, a deficiency in factor XI leads to a mild clotting abnormality, if at all. Hence, current views accept the proposal that the exposure of damaged vascular tissue initiates the clotting cascade in what historically was considered as the *extrinsic* clotting system. Damaged vascular tissue causes an immediate response with the induction of mRNA for TF. TF is a glycoprotein which is associated with the membrane of medial smooth muscle cells and adventitia. It has not been observed in the EC. However, it is inducible in the EC upon vascular injury, and exposure to thrombin. Other factors inducing enhancement of TF are platelets, granulocytes, macrophages, IL-1, and tumor necrosis factor α . Exposed TF binds to factor VII to form the TF-VII complex, a mostly inactive complex. It is activated by thrombin, which may be present in small amounts at the initial site of damage, as well as factor Xa. The TF-VII complex can also be activated by factors IXa and XIIa, and by its product, TF-VIIa, the latter being a positive feedback step. The TF-VIIa complex reacts with factor X on the membrane surface to transform factor X to the active factor Xa. Subsequently factor Xa activates

prothrombin into thrombin with the mediation of factor Va. (The TF-VIIa complex is inhibited by ATIII-heparin and by the Xa-TFPI complex.) The TF-VIIa complex has the capacity to activate factor IX to factor IXa.

Since TF-VIIa is capable of activating factor X, the necessity for the utilization of factor IX in the clotting system has been raised and addressed. However, individuals with deficiencies of factors VIII and IX do exhibit abnormal clotting times and clinical bleeding. Therefore, current beliefs suggest that the TF-VIIa complex activates both factors IX and X, and that factor IXa, in conjunction with factor VIIIa, activates factor X as the need arises in order for normal coagulation times to be experienced.

Fibrinolysis and its modulation

The fibrinolytic system is a process which modulates the degradation of the clot as the organism repairs and replaces damaged vascular tissue. This process encompasses the degradation of the fibrin clot and its cellular components to soluble degradation products. Many of the constituent zymogens, activators and enzyme inhibitors are either intimately located within the clot or within the adjacent endothelial tissue associated with the clot. t-PA is a secretory product of the EC whose secretion is promoted by thrombin. Its inhibitor, PAI-1 is also observed in ECs, as well as in platelets, plasma and the EC matrix. (PAI-2 has only been seen in extracts of placental tissue in the third trimester of pregnancy.) Plasminogen, the inactive zymogen for the fibrinolytic plasmin, is readily bound by thrombospondin, a glycoprotein produced by platelets and expressed to the membrane surface upon activation. Thrombospondin acts to inhibit interaction of plasminogen with fibrin, as well as the activation of the plasminogen-fibrin complex. Plasminogen is entrapped in the clot and acts locally upon appropriate activation. α_2 -AP is a component of the α granules of platelets. Accordingly, all the components necessary for fibrinolysis and its control are strategically placed at the site of the clot. Circulating α_2 -AP, for example, is not believed to penetrate the clot and affect fibrinolysis, whereas α_2 -AP in the entrapped platelet (granules) can be released upon activation of the platelets. Likewise, fibrinolysis occurs only within the clot, and not systemically. Hence, the postulated pathway for fibrinolysis and its modulation envisions the degradation of fibrin into soluble degradation products by plasmin. (Plasmin activity may be inhibited by α_2 -AP.) Plasmin is activated from the inactive plasminogen by two-chain t-PA. It may also be activated by two-chain u-PA and by kal-

likrein. The two-chain t-PA and two-chain u-PA are both generated from their one-chain precursors by plasmin. Kallikrein transforms the one-chain u-PA into its two-chain metabolite. PAI-1 and PAI-2 inhibit the catalytic activity of one-chain t-PA, two-chain t-PA and u-PA. Only PAI-2 inhibits one-chain u-PA. The activation of plasminogen to plasmin is also inhibited by lipoprotein(a), thrombospondin and histidine-rich glycoprotein (His-rich-GP).

A summary of the active proteases associated with coagulation and fibrinolysis, together with their naturally occurring inhibitors, is given in Table 1.

COBRA VENOM FACTOR

Carl-Wilhelm Vogel, Department of Biochemistry and Molecular Biology,
University of Hamburg, Hamburg, Germany

Cobra venom factor (CVF) is a constituent of cobra venom that specifically interacts with the serum complement system, causing its continuous activation. Whereas numerous studies on the effect of cobra venom on blood and blood components, including complement, were performed during the early part of this century, CVF was not purified until the late 1960s. The molecular interaction of CVF with the complement system became understood in subsequent years, simultaneously revealing the reaction sequence of the alternative complement pathway, and CVF has been extensively biochemically characterized. The molecule is a structural and functional analog of complement component C3. CVF is also often used to deplete laboratory animals in order to investigate biological functions of complement. The depleting activity of CVF has recently been exploited in animal models of xenotransplantation where it has been shown that complement is a major contributor to the hyperacute rejection of the transplanted organ. Another application of CVF is its use in antibody conjugates to introduce cytotoxic activity to monoclonal antibodies, e.g. as a concept for experimental immunotherapy.

Structure of CVF

Cobra venom factor has been isolated from the Asian cobra (*Naja naja*, including several subspecies: *N.n. naja*, *N.n. kaouthia*, *N.n. atra*) and the Egyptian cobra (*Naja haje*). The isolated proteins have been biochemically characterized and found to exhibit only minor structural differences. CVF is a three-chain glycoprotein with a molecular weight of

~136 kDa, as determined by equilibrium sedimentation. SDS polyacrylamide gel electrophoresis yields a molecular weight of ~149 kDa as the sum of the α chain (~68.5 kDa), β chain (~48.5 kDa), and γ chain (~32 kDa). The γ chain of CVF shows size heterogeneity, with usually 3–5 bands being detectable. The oligosaccharide portion of the molecule represents ~7.4% (w/w). The major oligosaccharide was found to be a fucosylated symmetric N-linked chain of the complex type with an unusual α -galactosyl residue at the nonreducing end. Circular dichroism spectroscopy revealed a secondary structure of CVF of 11% α helix and 47% β sheet. The molecule is an irregular and somewhat elongated ellipsoid structure with dimensions of 137×82 Å, as revealed by transmission electron microscopy.

More recently, the molecular cloning of CVF was accomplished using a cDNA library from cobra venom glands. The CVF mRNA contains a single open reading frame of 4926 nucleotides, coding for a single-chain preproprotein of 1642 amino acid residues. The mature three-chain protein is derived from the single-chain prepro-CVF by removal of a 22 residue signal peptide, an 83 amino acid peptide consisting of four arginine residues and a 79 amino acid peptide resembling a C3a anaphylatoxin generating the C-terminus of the CVF α chain and the N-terminus of the CVF γ chain, and of an approximately 279 residue peptide resembling the C3d domain of C3, yielding the C-terminus of the CVF γ chain and the N-terminus of the CVF β chain (Figure 1).

Several methods have been reported to purify CVF. Phospholipase A₂ has been identified as a common contaminant of CVF preparations. Certain uses of CVF require the removal of the contaminating

Figure 1 The two-chain structure of human C3 and the three-chain structure of CVF, indicating regions of homology (see text for further details).

phospholipase A₂; and several methods have been reported for that purpose.

The molecule is immunogenic, and antisera can easily be raised in several species of laboratory animals. These antisera can be used in antibody-based immunoassays for the detection and quantification of CVF. A simple hemolytic assay has been devised to determine the activity of CVF.

Molecular interaction of CVF with complement

When CVF is added to human or mammalian serum it activates complement and leads to complement consumption. It binds to factor B of the alternative pathway. When factor B is in complex with CVF, factor B is cleaved by factor D into Ba, the activation peptide, which is released, and Bb, which remains bound to CVF. The bimolecular complex CVF,Bb is a C3 convertase which cleaves C3 into C3a and C3b (Figure 2). CVF,Bb generated with CVF from *N. naja*, but not from *N. haje*, is also a C5 convertase, cleaving C5 into C5a and C5b. The generated C5b will consume the terminal complement components in plasma by formation of the membrane attack complex. In conclusion, through the formation of the CVF,Bb enzyme CVF will consume C3, C5 and the

terminal complement components, leading to the depletion of complement activity in serum.

Functional and structural similarity of CVF and C3

The formation and function of the CVF-dependent C3 convertase is analogous to the formation and function of the C3b-dependent C3 convertase which is formed during activation of the alternative pathway of complement (Figure 2). Both enzymes, CVF,Bb and C3b,Bb are C3/C5 convertases, consisting of a structural subunit (CVF or C3b) and the identical active site-bearing subunit Bb. Despite this similarity, the two enzymes exhibit several functional differences. The C3b,Bb enzyme is very short lived with a half-life of decay into the two inactive subunits of 1.5 min, while the CVF-Bb enzyme is rather stable, with a decay half-life of 7 h. In addition, the C3b,Bb enzyme is subject to rapid and efficient regulation by the complement components factor H and I. Factor H dissociates C3b,Bb and serves as cofactor for the proteolytic inactivation of C3b by factor I. In contrast, the CVF,Bb enzyme and CVF are completely resistant to the regulatory actions of factors H and I. Due to these two properties, the CVF,Bb enzyme is stable and present in plasma for prolonged periods of time. This is the basis for its ability to activate efficiently, and thereby consume, complement in serum.

Extensive structural homology has been found between CVF and mammalian C3. The structural homology includes immunologic cross-reactivity, similar amino acid compositions, similar secondary structures, and a similar shape and dimension under the electron microscope. The N-termini of the three chains of CVF show sequence homology with human C3, leading to the conclusion that the CVF α chain and the C3 β chain are homologous structures, and

Figure 2 Formation and enzymatic activity of alternative pathway C3 for convertases, CVF,Bb and C3b,Bb.

that the CVF β and γ chains are derived from a C3 α chain (Figure 1). Molecular cloning has recently confirmed the chain relationships and structural homology of CVF and C3.

Both C3 and CVF code for single-chain precursor molecules which are then processed to yield the mature two-chain C3 or three-chain CVF, respectively. The sequence identity between pre-pro-CVF and mammalian pre-pro-C3 molecules on the protein level is ~51% and increases to ~70% if one allows for conservative amino acid replacements. In the case of pre-pro-C3 from cobra the similarity at the protein level is 91.6%, corresponding to a sequence identity on the DNA level of 93.3%. These results strongly suggest that the gene for CVF was generated by gene duplication from a C3 gene.

Use of CVF as an experimental tool to study the biological functions of complement

Cobra venom factor can be safely administered to laboratory animals. With the exception of an acute and transient reaction due to massive complement activation at high dosages, no toxic effects of CVF are known. Injection of CVF causes consumption of complement components *in vivo* and depletes complement activity in the plasma of treated animals. The complement activity will remain low for 1 to several days, and resynthesis of consumed complement components will restore normal complement activity within 5–10 days. Accordingly, temporary suppression of complement activity by CVF has become a widely used experimental tool for studying the biological functions of complement by comparing normal with complement-depleted animals. Questions addressed include the role of complement in the generation of an immune response, in host defense against infections and in the pathophysiology of disease.

Antibody conjugates with CVF

The property of the CVF, Bb enzyme to activate complement exhaustively has been exploited for the selective killing of tumor cells by coupling of CVF to monoclonal antibodies with specificity for surface antigens of tumor cells. Antibody conjugates with CVF will target CVF to the cell surface where the CVF, Bb enzyme forms from complement factors B and D of the host complement system. The antibody-bound and therefore cell surface-bound CVF, Bb enzyme will continuously activate C3 and C5 and

elicit complement-dependent target cell killing through the formation of membrane attack complexes. Antibody conjugates with CVF have been shown to kill human melanoma cells, human lymphocytes and leukemia cells, and human neuroblastoma cells. The concept of coupling CVF to monoclonal antibodies seems particularly promising in light of the fact that many monoclonal antibodies against tumors bind with good specificity but do not activate biological effector mechanisms such as complement. The coupling of CVF to monoclonal antibodies therefore introduces a biological effector function to the antibody.

Outlook

As CVF is a structural analog of C3, it may be possible to engineer a human C3 derivative that has the property of CVF to form a stable C3/C5 convertase. Such a 'human CVF' can be expected to be significantly less immunogenic. A 'human CVF' might be a useful therapeutic agent for modulating the complement activity in certain diseases where complement is known to be involved in the pathogenesis. One particular application of a 'human CVF' might be the depletion of complement in patients prior to xenotransplantation. 'Human CVF' could also be used in antibody conjugates as an immunotherapeutic agent in cancer patients.

COCCIDIOIDES, INFECTION AND IMMUNITY

Jon E Lutz, David W Denning and David A Stevens, Department of Medicine, Division of Infectious Diseases, Santa Clara Valley Medical Center, California, USA

Coccidioidomycosis is a fungal disease of humans and animals caused by the dimorphic fungus *Coccidioides immitis*. It is acquired by inhalation of arthroconidia in the southwestern USA and Central and South America. After exposure, most infected persons (60%) are asymptomatic and some 40% will develop a primary illness, usually pneumonic. Most of these resolve without sequelae. Up to 8% of infected individuals will have prolonged or later emergence of disease with, usually, pulmonary nodules or cavities (5%), but occasionally (1%) meningitis, osteomyelitis, cutaneous, lymph node, urogenital and other disease sites affected. Men, pregnant women, immunocompromised hosts, Blacks and persons of Filipino ancestry (dissemination 175 times more common than Whites) tend to have a higher frequency of dissemination and more severe disease. Disseminated and chronic forms of the disease require therapy. The mortality of coccidioidal meningitis is reduced by treatment from 100 to 30%. Pathologically, the spherule (the tissue phase of the fungus), which may contain many endospores, is surrounded by varying degrees of granulomatous reaction with or without caseation.

Antigens

At least 15 antigens can be found on immunoblots of SDS-PAGE gels from both soluble mycelial and spherular extracellular preparations. These include the tube precipitating antigen (detected by immunoglobulin M (IgM) antibody) which is a mycelial phase glycoprotein containing about 20% protein and the sugars 3-O-methylmannose (unique to *C. immitis* among pathogenic fungi), mannose and glucose, and the antigen recognized by complement fixing IgG antibody, a 110 kDa protein which runs at 48 kDa in a denaturing gel. IgM and IgG antibodies can also react in immunodiffusion with these two

specific antigens. These two antigens are present in both fungal phases. Recently, a 33 kDa protein antigen has been purified, its gene cloned and expressed in bacteria. It is distinct from the antigens used in conventional complement fixation, tube precipitin and immunodiffusion procedures. It has been localized to the inner conidial wall of arthroconidia, within the cell wall and septa of spherules and on the wall surface and interconnecting glycocalyx of endospores.

Cellular and cytokine responses

T lymphocyte responses to *C. immitis* are critical for host defense. Thymectomy in rodents leads to severe disease. Immunity can be transferred to naive mice by infusions of T cells from immune mice. Patients infected with human immunodeficiency virus (HIV) who develop coccidioidomycosis have low CD4 T cell counts, median <150 cells per cubic millimeter. Macrophage killing of arthroconidia by enhanced phagosome-lysosome fusion only proceeds (in mice) in the presence of antigen-stimulated T lymphocytes or soluble mediators produced by these T cells. Natural killer cells are able to kill endospores and spherules *in vitro*.

DBA/2 mice are relatively resistant to *C. immitis*; BALB/c mice are highly susceptible. The lungs of infected DBA/2 mice have relatively increased interleukin 6 (IL-6) and interferon γ (IFN γ) and their splenocytes produce greater amounts of tumor necrosis factor α (TNF α), IL-6 and IL-1 α in response to stimulation with formalin-killed spherules *in vitro*. Treatment of the DBA/2 mice with an IFN γ -specific monoclonal antibody (mAb) increases their susceptibility. Infected BALB/c mice have increased levels of IL-4 in the lungs. Treatment of BALB/c mice with an IL-4-specific mAb provides significant protection. Treatment of susceptible BALB/c mice with recombinant IFN γ provides significant protection. *In vitro*,

treatment of murine peritoneal or alveolar macrophages with rIFN γ augments anti-*Coccidioides* activity.

Independent of the immune status of the donor, human peripheral blood monocytes phagocytose arthroconidia and inhibit growth of the fungus and kill it. Monocytes may therefore play a role in limiting infection before a specific immune response develops. Peripheral blood mononuclear cells from skin test-positive individuals display increased lymphocyte transformation, IL-2 production and IFN γ production in response to spherule antigen. Spherules and arthroconidia elicit production of TNF α from human monocytes *in vitro*. TNF α alone or in combination with IFN γ enhances killing of spherules by human monocytes *in vitro*. The cytokine responses of a small number of patients with overwhelming infection with *C. immitis* have been studied. IL-1 and IL-2 were undetectable but levels of TNF α and IL-6 were elevated. T Lymphocyte coccidioidal-specific responses are suppressed in some patients and various lines of evidence suggest that antigen overload, specific suppressor T lymphocyte activity, circulating humoral suppressive substances and spherule-produced suppressive substances may all be involved.

A positive skin test is a marker of previous infection, and remains positive for life in the absence of severe immunosuppression such as the acquired immune deficiency syndrome (AIDS). Spherule-phase antigens may be more sensitive in eliciting cell-mediated responses. Cell-mediated responses *in vitro* are mirrored by intradermal skin testing which correlates reasonably well with clinical outcome – persons with disseminated disease are often anergic and those who are anergic are more likely to have a poor outcome.

Arthroconidia, endospores and particularly spherules are ordinarily quite resistant to killing by neutrophils or products of oxidative metabolism. A residual hyphal wall layer on arthroconidia and an extracellular matrix (acidic glycoproteins which are both carboxylated and sulfated) surrounding spherules and endospores appear to protect the fungus from phagocytosis and killing. Neutrophils comprise part of the initial response to arthroconidia in the lower airways and inhibit the growth of arthroconidia. Phagocytosis of arthroconidia and endospores is augmented by immune serum. Neutrophils fail to kill any phase of *C. immitis* unless immunologically activated, such as by IFN γ , in which instance they are capable of killing endospores but not arthroconidia. There appears to be some strain-to-strain variation in intrinsic susceptibility to neutrophil activity.

Humoral responses

Both asymptomatic infection and disease are marked in over 90% of all infected persons by an antibody response to *C. immitis*. Mycelial phase antigens are most useful in serodiagnosis. IgM is detected earliest by precipitation, latex agglutination or immunodiffusion in 75% of infected individuals. Detectable IgM usually disappears within 6 months of infection. In identifying progression of disease, IgG is useful: elevated titers indicate dissemination, and titers will fall with successful therapy in serum and in cerebrospinal fluid (CSF) in patients with meningitis. Antibody to the 33 kDa antigen can be detected in the CSF of patients with *Coccidioides* meningitis, including about half of those without detectable coccidioidal complement-fixing (CF) antibody. The antibody against the antigen appears to persist longer than detectable CF antibody. For patients who were failing therapy, a significant increase in antibody to the 33 kDa antigen was demonstrated over time; for patients responding to therapy, a significant decrease. Circulating immune complexes are found in up to 70% of patients with active, disseminated disease. Circulating free antigen has also been detected in patients with active disease. Total serum hemolytic complement activity is depressed early in primary infection in some patients but later recovers. Both classic and alternate pathways are probably activated.

Hypersensitivity

Erythema nodosum may occur during the primary infection and is a marker of hypersensitivity to coccidioidal antigens. Serum IgE is elevated in patients with active disease and tissue eosinophilia (or eosinophilic pleocytosis in CSF) may accompany severe disseminated disease.

Immunosuppression

Solid organ transplantation, corticosteroid therapy and AIDS may lead to severe, often fatal, disease, due to either recent infection or reactivation. The serologic response in compromised hosts is usually, but not always, at least qualitatively intact.

Vaccines

Formalin-killed spherule vaccine is highly effective in a murine model. Unfortunately, a recent trial of formalin-killed spherules in humans failed to demonstrate a significant protective effect. Work is proceeding to identify protein immunogens as potential vaccines.

COCCIDIOSIS

David A Stevens, Santa Clara Valley Medical Center, San Jose, California, USA

Coccidiosis is the generic term given to the disease caused by infection of domestic animals with *Eimeria* species. These are apicomplexan protozoa that parasitize mainly epithelial cells, principally those of the intestinal tract. They exhibit a high degree of host and site specificity and it is usual for a given species of animal to be host to several different *Eimeria* spp., each with its distinct location in the gut. Because of the self-limiting nature of the life cycle and the potential of the host to develop resistance to reinfection, coccidiosis is rarely a problem in nature but may be important in highly intensive systems of animal husbandry. In modern poultry production, where it is estimated to cause annual losses of \$US1.5 billion, most flocks are prophylactically medicated. In humans, closely related organisms (*Isospora* spp.) cause a similar, but rarely significant, condition.

Characteristics of the organism and its antigens

The complex life cycle is monoxenous and sporozoan. Within the host, a period of asexual replication (schizogony) is followed by a sexual phase (gametogony). The number of cycles of schizogony, usually fixed, varies with the species but is commonly three or four, the last being followed by the formation of gametes (Figure 1). After fertilization, the zygote, protected within a resistant shell (oocyst), is voided in the feces. A period of maturation outside the host (sporogony), including a meiotic nuclear division, is necessary for the oocyst to become infective. Transmission is fecal–oral.

Infection causes enteritis of varying severity, depending upon the number and the biology of the

Figure 1 Life cycle of *Eimeria* species. (Reproduced with permission of Springer-Verlag GmbH & Co. KG from Rose ME (1985) *The Eimeria*. In: Parkhouse RME (ed) *Parasite antigens in protection, diagnosis and escape*. *Current Topics in Microbiology and Immunology* 120: 7–17.

Eimeria spp. ingested. Those that develop in crypt epithelium, resulting in hemorrhage, are highly pathogenic and may cause serious mortality. Anorexia and stunted growth are common consequences of infection.

The various developmental stages of the parasite are morphologically distinct and possess both stage-specific and common antigens. Some of these have been purified and characterized, mostly those from species parasitizing the domestic fowl, such as *E. tenella* and *E. maxima*. The emphasis has been on the initial infective stage, the easily accessible sporozoite; this is a major target for immune inhibition and, once development has been initiated, is capable of inducing immunity.

Sporozoite antigens of current interest are those associated with some of the organelles, i.e. the refractile globule and those forming the apical complex (rhoptries, dense granules and micronemes) and presumably involved in invasion of the host cell. Treatment with a refractile body antigen of 26–28 kDa has been reported to protect chickens against challenge infections with four different *Eimeria* spp.; similar antigens are present in sporozoites of *E. bovis* (infecting cattle), becoming distributed within the cytoplasm of the invaded host cell. Rhoptry polypeptides migrate in the 45–65 kDa range and differ anti-

genically between species, paralleling the species-specificity of immunity induced by infection. A merozoite protein from *E. maxima* of 230 kDa has been reported to induce maternally transmissible immunity (to homologous and heterologous challenge), as have gametocyte-derived 56, 82 and 230 kDa antigens of the same species.

Immune responses of the host

Species of *Eimeria* differ widely in the degree of resistance to challenge induced by infection, even within the same species of host. Immunity induced in this way is species- and, in some cases, strain-specific but other methods of immunization, e.g. injection of purified antigens (above), may produce heterologous protection. The specificity, or otherwise, of immunity to the different developmental stages is not known.

Immunity is T cell mediated, apparently with little involvement of natural killer cell activity or reactive oxygen/nitrogen intermediates. Both humoral and cell-mediated immune responses participate in resistance but the latter is the more important. Antibodies are probably most effective against extracellular parasites, thereby reducing invasion. Experimentation in mice has shown that CD4⁺ T lymphocytes, which play the major role in controlling primary infections, are able to do so without the participation of inflammatory cells, and that CD8⁺ lymphocytes appear to be more important in the later stages of infection. The cytokine-release profile of responding lymphocytes does not indicate any correlation between T_H1 and T_H2 type responses and resistance/susceptibility. Although IFN γ , acting via the host cell, is very effective in halting the development of the parasite, it does not seem to mediate the prompt suppression seen in immunized animals. Work in chickens indicates that this may be due to the action of CD8⁺ lymphocytes in preventing sporozoites from reaching their developmental site in crypt enterocytes.

Evasive strategies by the organism

Eimerian coccidia are not known to use mechanisms for avoiding the immune response of the host. The brevity and finite nature of the life cycles, coupled with antigenic differences between the developmental stages, probably accounts for the ability of the parasite to complete its cycle, relatively unhindered, in the naive host; however, in a few (unusual) species additional asexual cycling occurs in immunocompromised hosts.

Some *Eimeria* spp. isolated from chickens in geo-

graphically distinct areas may show intraspecific variation, demonstrable by incomplete cross-protection, but their antigens have not been studied. Variation of this type has not been induced experimentally, nor has it emerged over time in any one site.

Vaccines

Vaccination, as a means of controlling coccidiosis, is an attractive alternative to prophylactic medication which is, inevitably, accompanied by the emergence of drug-resistant strains of the parasite. Until recently the only type of 'vaccine' commercially available (for chickens) consisted of wild-type, fully virulent organisms. Now there are two vaccines whose constituents have been attenuated by selection for abbreviated developmental cycles, or by adaptation to growth in developing chicken embryos. These are being successfully used in various types of flocks but, in view of their cost, are likely to be most useful for breeders and layers. The possibility of deriving live, attenuated strains suitable for vaccinating rabbits or sheep is being pursued.

Although live vaccines are effective, for reasons of cost, convenience (e.g. shelf-life) and safety, the ultimate goal of immunoprophylaxis for coccidiosis must be the availability of subunit vaccines, produced by recombinant DNA technology. Crude parasite extracts (primarily of sporozoites), given parenterally or orally, are capable of inducing protection against subsequent homologous challenge infection,

but the results are influenced by the resistance phenotype of the host. Various purified candidate peptide antigens have afforded partial protection, either when given directly or via the hen (above).

COLD AGGLUTININS

Ten Feizi, Glycosciences Laboratory, Imperial College School of Medicine, Northwick Park Hospital, Harrow, UK

Cold agglutinins are autoantibodies of low affinity which agglutinate erythrocytes at temperatures below 37°C, and optimally at 4°C. Sera of the majority of healthy adults contain harmless cold autoagglutinins at low titers (1 : 2 to 1 : 32). Sera of newborns usually do not contain cold agglutinins; they become detectable during the first year of life. The majority of these naturally occurring autoantibodies are directed at the I or i antigens. Raised levels of cold agglutinins occur a) transiently following certain infections, for example with *Mycoplasma pneumoniae* and Epstein–Barr virus (anti-i), and b) persistently in a chronic relatively benign lymphoproliferative disorder termed chronic cold agglutinin disease. Raised levels of cold agglutinins may go

unnoticed, and are frequently detected incidentally during blood cross-matching or other hematological investigations. The antibodies of certain individuals however, cause clinical symptoms: cyanosis (blueness) with impaired circulation at the extremities upon exposure to the cold resulting from erythrocyte autoagglutination, or an autoimmune hemolytic disorder associated with a positive Coombs' (antiglobulin) test resulting from coating of erythrocytes with the complement components C3 and C4. The severity of the symptoms does not necessarily correlate with the cold agglutinin titers measured at 4°C, rather it is thought to be a reflection of the relatively high binding affinities of the antibodies in certain patients.

Restricted clonality and cross-reactive idiotypes

Cold agglutinins have been the subject of considerable interest since the late 1950s when it was realized that they are usually monoclonal or oligoclonal antibodies. Those occurring in chronic cold agglutinin disease are almost always monoclonal, but even the transiently occurring, postinfective cold agglutinins, when isolated with care to avoid contamination with serum immunoglobulins, have been found to be monoclonal or oligoclonal antibodies. Cold agglutinins with anti-I and anti-i specificities are almost always of the IgM class; the majority have κ light chains, and only a minority, λ . Cold agglutinins with other specificities, designated anti-Pr, anti-Gd, anti-Fl etc. occur less commonly. The majority of these are also of the IgM class but several monoclonal IgA and IgG have been described.

There is a predominance of κ light chains among monoclonal anti-I, whereas λ chains are not uncommon among anti-i and other types of cold agglutinin. Cold agglutinins were the first antibodies among which cross-reactive idiotypes were demonstrated. Two distinct idiotypic systems have been described: one found among anti-I and anti-i, and a second among anti-Pr antibodies; the latter included proteins of the IgM and IgA classes. The first demonstration of idiotypic antigens on blood lymphocytes corresponding to those serum antibodies in the same individuals was made in patients with cold agglutinin disease. The idiotypic antigens among anti-I and anti-i are located predominantly on the variable regions of their heavy chains. Restricted V_H and V_L subgroups are represented among these antibodies, and the cross-reactive idiotypes are almost certainly associated with the framework rather than the complementarity determining regions, since an occasional myeloma protein lacking erythrocyte cold agglutinin activity also has been found to express the same idiotypic determinants.

Combining specificities towards carbohydrates

The I and i antigens are expressed in a developmentally regulated manner on human erythrocytes. In neonates i predominates, and in adults I. The level of i decreases on erythrocytes in the course of the first year of life while I increases. These antigens were the first among developmentally regulated antigens to have been characterized at the molecular level. They are carbohydrate structures: i is expressed on a linear hexasaccharide sequence (structure 1, **Figure 1**) consisting of alternating galactose and N-acetyl-

Figure 1 Schematic representation of oligosaccharide sequences which express the i and I antigens and are the most common targets of cold agglutinins. These sequences occur as the backbone domains of oligosaccharides that are O- or N-linked to proteins, or linked to lipids. Also shown are examples of several related oligosaccharides which are based on the i and I backbones and express the major blood group antigen A, B and H, or carbohydrate differentiation antigens SSEA-1 (also designated Le^x or CD15) and sialyl-SSEA-1. The latter two structures are among ligands for leukocyte to endothelium adhesion molecules, the selectins. *Mycoplasma pneumoniae* binds to oligosaccharide structures 7 and 9, but with a stronger affinity for the latter. Symbols for monosaccharides: ○, galactose-β; ●, galactose-α; ◐, N-acetylglucosamine-β; ▽, fucose-α; ⊙, N-acetylgalactosamine-α; □, N-acetylneuraminic acid-α. The numbers over the glycosidic bonds indicate the positions of linkage of the monosaccharides.

glucosamine residues, and I on the related branched octasaccharide (structure 8). Each monoclonal antibody recognizes a particular domain on these oligosaccharide sequences. These sequences occur not only on glycoproteins but also on glycolipids. They are not confined to erythrocytes, but have differing patterns of expression in various tissues of the body. They occur not only as accessible structures but also as internal structures (backbone structures) of the major blood group antigens A, B and H. As illustrated for the i sequence, fucosylation at galactose masks the i antigen activity but gives rise to the blood group H antigen (structure 2). In blood group A

persons there occurs addition of an N-acetylgalactosamine residue to the H antigen structure to form blood group A (structure 3), and in B individuals there is a galactose residue instead of N-acetylgalactosamine (structure 4). Less detailed information is available on the target antigens of cold agglutinins anti-Pr, Gd, etc. The majority of these are directed at various sialo-oligosaccharide sequences on glycoproteins or glycolipids. For example anti-Gd binds to structure 7 on glycolipids.

Clues to pathogenesis

What triggers the production of cold agglutinins? Why are they monoclonal? The precise details are not yet known. The transient cold agglutinin syndrome that follows *M. pneumoniae* infection offers a unique opportunity to study aspects of the mechanism of stimulation of anti-I production. Negligible amounts of I antigen can be detected on cultured *M. pneumoniae*, and there is evidence that this represents passively adsorbed material, probably in association with other lipids and glycolipids, from the serum. As autoantibodies to other glycolipids in the serum, e.g. those with blood group A, B, H, and Lewis activities, do not prevail in this infection, it is unlikely that the anti-I are directed against this passively adsorbed form of the I antigen. On the other hand, the receptors on host cells to which the mycoplasma adheres are sialo-oligosaccharide sequences such as structures 7 and 9, that are based on backbones of Ii type, the highest affinity binding being to the branched I type, structure 9. It seems likely that the selective production of high titer anti-I (i.e. 'antireceptor' antibodies) following *M. pneumoniae* infection is somehow related to these interactions. Possibly the lipid rich mycoplasma serves as an adjuvant overcoming tolerance to self-antigen I. It should be noted that the sialo oligosaccharide receptor sequences occur not only on erythrocytes but also on B and T lymphocytes as well as monocytes, for example. Thus there remains considerable scope for dissection of the macromolecular interactions that culminate in the production of auto-anti-I.

Clues to the biological importance of the target antigens of cold agglutinins and related carbohydrate structures

More recent work with hybridoma-derived monoclonal antibodies that were raised to differentiation antigens of human leukocytes and other cell types, and to various tumor-associated antigens of epithelial tissues has shown that the I and i sequences constitute backbone structures of an array of differ-

entiation antigens and tumor-associated antigens in addition to the blood group antigens discussed above. For example, fucosylation of the penultimate N-acetylglucosamine as in structure 5 forms the antigen that has been variously designated SSEA-1, Le^x or CD15. This antigen is a stage-specific embryonic antigen (SSEA-1) in the mouse; it is a distinctive marker of granulocytes (CD15) in the human, while the corresponding sialylated structure which occurs on monocytes as well as granulocytes is also a tumor-associated antigen in certain epithelial malignancies.

Much progress is being made in the cloning of the glycosyltransferases that give rise to this family of oligosaccharides. There is much current interest in the fucosylated and sialylated oligosaccharides in this series (e.g. structures 5 and 6) as ligands for the endothelium to leukocyte adhesion molecules, the selectins which have important roles in leukocyte recruitment to sites of inflammation.

Conclusions

Cold agglutinin syndrome on the one hand presents excellent opportunities for studying mechanisms that operate in the generation of an autoimmune response in humans. On the other hand, the carbohydrate sequence-specific monoclonal autoantibodies in this disorder have served as remarkable reagents, and work with these antibodies opened the way to a whole new field of carbohydrate onco-developmental antigens, a field that expanded rapidly with the advent of the hybridoma technology and advanced further with the demonstration of roles for oligosaccharides as ligands in biological recognition.

COLONY-STIMULATING FACTORS

John W Schrader, The Biomedical Research Centre, UBC, Vancouver, Canada

Colony-stimulating factor (CSF) is the operational term for a class of molecules that stimulate hematopoietic progenitor cells to divide and generate colonies of differentiated progeny such as neutrophils or macrophages. Colony-stimulating factors were originally detected and assayed by culturing a source of hematopoietic progenitor cells, such as a cell suspension derived from the bone marrow, in medium that has been jellified by the addition of a substance such as agar or methyl cellulose. Provided a CSF or a source of a CSF is present, hematopoietic progenitors survive and grow, and over a period of a week or so, give rise to colonies of 100–10 000 differentiated cells. The number of colonies and the extent to which a preparation can be diluted and still retain activity, can be used to quantitate the CSFs in that preparation. Moreover the morphology of the differentiated cells in the colonies can be determined by picking off and staining the colonies or by staining the whole culture.

Colony assays were developed in the 1960s by Pluznik and Sacks and Bradley and Metcalf, and have in large part provided the data that have generated our current picture of the molecular regulation of hematopoiesis and of the cellular steps in the differentiation of hematopoietic cells. Colony assays also have allowed the identification of different types of committed progenitor cells and determination of their physical and antigenic characteristics.

All CSFs share three basic properties:

- 1 they support the survival of hematopoietic progenitor cells and mature cells such as neutrophils by suppressing apoptosis;
- 2 they stimulate growth of stem/progenitor cells and in some cases of mature cells, e.g. mast cells or macrophages;
- 3 they regulate the function of cells, for example activating mature granulocytes.

Nomenclature

Originally, CSFs were given names that reflected in some measure their function. Thus a preparation that stimulated progenitor cells and generated colonies containing both neutrophils and macrophages was said to contain granulocyte-macrophage CSF (GM-CSF); one that stimulated the growth of colonies containing only neutrophils was said to contain granulocyte CSF (G-CSF). The various CSFs are now recognized as members of a large family of cytokines and hormones united by a common evolutionary origin and similarities in their three-dimensional structure (discussed below). Both GM-CSF and G-CSF have gained wide acceptance as names of two, well-characterized molecules that have been produced in large quantities by recombinant DNA techniques and are now in clinical use. It should be noted, however, that activities of these molecules can be broader than implied by their name or by their action in one particular species. Thus whereas in the mouse, GM-CSF generates colonies containing neutrophils and macrophages, in the human it also generates colonies of eosinophils. Likewise, not only does G-CSF stimulate the growth of progenitors of neutrophils, but it also affects more primitive cells. Interleukin 3 (IL-3) acts as a CSF with a broad target range and the capacity to stimulate progenitors of megakaryocytes, mast cells, eosinophils, macrophages, neutrophils, basophils and erythroid cells, as well as those multipotent progenitors generating colonies containing various mixtures of these cell types. Because of these properties IL-3 has also been termed 'multi-CSF'. A fourth CSF, widely called CSF-1, stimulates colonies of macrophages and has also been termed macrophage CSF (M-CSF). As noted below CSF-1 differs slightly from the GM-CSF, G-CSF and IL-3 in its overall molecular structure and greatly in the type of cell surface receptors that it stimulates. It also differs from the other CSFs in that it occurs in the blood-

stream in normal animals and in that it has targets outside the lymphohematopoietic system, in the female reproductive tract.

It should be noted that operationally a number of different CSFs can stimulate one type of hematopoietic cell (Table 1). For example, a colony of macrophages can develop from a macrophage progenitor that has been stimulated by GM-CSF or by IL-3, or by CSF-1. Thus, in the earlier literature, prior to the molecular characterization of CSFs and the subsequent development of specific neutralizing antibodies, an activity that was referred to operationally as 'GM-CSF' may in fact have reflected the presence, not of the molecule now defined as GM-CSF, but instead of another molecule such as IL-3 that could also stimulate the development of colonies containing neutrophils and macrophages. Likewise, in earlier studies, the reader will encounter terms such as 'eosinophil CSF' or 'megakaryocyte CSF'. No distinct molecular species that specifically stimulate the development of large colonies of eosinophils or megakaryocytes have yet been characterized. Many of the earlier studies of eosinophil CSF or megakaryocyte CSF were assaying the ability of IL-3 to stimulate colonies of these cells.

Other molecules are able to stimulate progenitor cells and act operationally as CSFs. In the human, but not the mouse, IL-5 can stimulate the growth of small colonies of eosinophils although its major action appears to be to enhance differentiation of eosinophils. Under some circumstances, IL-6 can give rise to small colonies. Steel locus factor (SLF) or stem cell factor, which is the ligand of the c-kit protein, can stimulate the growth of small colonies of mast cells and of neutrophils.

An important principle is that mixtures of factors often exert synergistic effects on colony formation.

Interleukin 3 and CSF-1, for example, in the human strongly synergize in the production of macrophage colonies. Other peptide regulatory factors such as SLF, IL-1, IL-6 and IL-4 all have been reported to have synergistic activity in colony formation in various situations. IL-11 and thrombopoietin synergize with other cytokines in generating colonies of various hematopoietic lineages, but have a particular propensity to stimulate the generation of megakaryocytes and platelets.

Sources

The colony-stimulating factors are made in many cell types, including epithelial cells, endothelial cells, fibroblasts, smooth muscle cells and cells of the hematopoietic system, in particular T lymphocytes. In general, CSFs are only produced in response to stress, for example infection, although there are exceptions such as SLF or CSF-1, which are produced in the body under normal conditions. Microbial products such as endotoxin or nucleic acids are potent stimuli for CSF production. Other peptide regulatory factors such as IL-1 can induce the production of colony-stimulating factors, for example GM-CSF, from cells such as endothelial cells or fibroblasts. The antigen-activated T lymphocyte is a source of two CSFs: GM-CSF and IL-3. Macrophages can produce GM-CSF, G-CSF and CSF-1. When stimulated by LPS B lymphocytes produce small amounts of GM-CSF. Mast cells and eosinophils produce small quantities of IL-3, IL-5 and GM-CSF when activated by cross-linking the Fc receptor for immunoglobulins.

Table 1 Stimulation of proliferation and differentiation of hematopoietic cells by colony-stimulating factors

Target cells acted on in bone marrow	Multi-CSF (IL-3)	GM-CSF	G-CSF	M-CSF (CSF-1)
Pluripotent stem cell	+	(+)	(-)	(-)
Granulocyte-monocyte progenitor	+	+	+	(+)
Monocyte progenitor	+	+	-	+
Neutrophil progenitor	+	+	+	-
Eosinophil progenitor	+	+	-	-
Basophil progenitor	+	+	-	-
Mast cell	+	-	-	-
Megakaryocyte	+	-	-	-
Erythroid progenitor	+	+/-	-	-
Lymphoid				
B progenitor	+	-	-	-
T progenitor (thymus)	-	-	-	-

Physiological role of CSF

Physiologically, the CSFs can be regarded as part of a larger family of peptide regulatory factors or cytokines that play a major role in regulating the body's response to infection or injury. A general characteristic of the CSFs is that they stimulate not only the growth of progenitor cells leading to production of various differentiated progeny, but also the effector functions of the mature differentiated cells. Thus GM-CSF can prime for a respiratory burst in neutrophils, and GM-CSF and IL-3 can enhance phagocytosis by macrophages.

Some of the CSFs have been shown to enhance immune responses. Both GM-CSF and IL-3 have these effects which probably are mediated via actions on accessory cells. For example, IL-3 induces the release of substances such as IL-1 from macrophages and upregulates the expression of class II major histocompatibility complex antigens. GM-CSF, with IL-4, promotes the differentiation of monocytes to dendritic cells.

A minority of CSFs have a role in the normal development of the hematopoietic system as opposed to its activation during stress. Mice with mutations blocking production of CSF-1 exhibit defects in the development of macrophages and osteoclasts. Genetic lesions in SLF or its receptor leads to defects in the development of erythrocytes and mast cells as well as in nonhematopoietic tissues. In the absence of GM-CSF, a lung disease called alveolar proteinosis occurs.

Structure of the CSFs

The CSFs are small polypeptides of M_r around 15 000 which are heavily and variably modified by glycosylation, although the functional significance of this carbohydrate has not been established. IL-3, IL-5, GM-CSF, G-CSF erythropoietin, thrombopoietin and IL-11 are monomers, whereas CSF-1 and SLF are homodimers, linked by disulfide bonds. As discussed below, CSF-1 and SLF also differ from the other CSFs in binding to a different structural class of cell surface receptors. Although there are few similarities in the amino acid sequences of different CSFs, analysis of their three-dimensional structures has revealed that they all belong to one structural family of proteins, characterized by four α helices, bundled in a particular way. This family also includes most interleukins, as well as hormones such as growth hormone, thrombopoietin, erythropoietin and leptin.

IL-3, GM-CSF and G-CSF bind to members of a structural family of receptors termed the cytokine receptor superfamily, members of which also bind

IL-2, erythropoietin, IL-4, IL-5, IL-6 and IL-7, as well as other cytokines such as LIF, CNTF and leptin.

GM-CSF and IL-3 each bind with low affinity to specific receptor α chains belonging to this cytokine receptor family. High-affinity binding and signal transduction, however, depends upon interaction with a second β receptor chain, which is also a member of the cytokine receptor family and is a common component of the receptors for IL-3, GM-CSF and IL-5. Ligand-binding induces or stabilizes dimerization of α and β chains leading to activation of cytoplasmic tyrosine kinases that associate with the intracytoplasmic portions of these chains. Activation of these tyrosine kinases, which include members of the JAK and Src families of kinases, triggers a cascade of intracellular events that regulate cellular growth, survival and differentiation.

The receptors for CSF-1 and SLF do not belong to the cytokine receptor family, but instead to a distinct family of receptors that are characterized by immunoglobulin-like domains in the extracellular portion of the molecule, and a tyrosine kinase domain in the intracytoplasmic part of the molecule. These receptors resemble those for platelet-derived growth factor and, more distantly, insulin. Ligand-induced dimerization of the CSF-1 and SLF receptors leads to activation of the intrinsic kinase activity of the receptors themselves. Despite these differences in the two major families of receptors used by CSFs, ligand binding in both cases triggers activation of the same intracellular paths that regulate cellular growth and apoptosis. Much more is known about the similarities of the intracellular signals activated by CSFs than their differences.

Clinical use

G-CSF and GM-CSF are already at a relatively advanced stage of their clinical evaluation. They have proven their value in accelerating the recovery of white blood cell counts following myelotoxic procedures such as bone marrow transplantation or chemotherapy. Further indications, for example in the treatment of infections, are being explored. Given the role of colony-stimulating factors in inflammatory processes, it is possible in the future that small molecules that antagonize their action will find use as modulators in diseases in which inflammation plays a role. Thrombopoietin (TPO) – also known as megakaryocyte growth and differentiation factor or megapoeitin – is a new member of the four-helix bundle cytokine family that is able to stimulate increases in levels of platelets in normal animals. In myelosuppressed animals TPO also stimulated recovery of neutrophils, probably reflecting the synergistic

effects of combinations of TPO and other hematopoietins on the *in vitro* proliferation of hematopoietic progenitors of multiple lineages. Administration of IL-11 also accelerates recovery of platelet levels in myelosuppressed animals and, like TPO, also accelerates the regeneration of neutrophils.

COMMON VARIABLE IMMUNODEFICIENCY

Thomas A Selvaggi, Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland, USA

Michael C Sneller, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland, USA

Common variable immunodeficiency (CVI) is a heterogeneous syndrome characterized by hypogammaglobulinemia and recurrent bacterial infections. This rare syndrome has an estimated prevalence ranging from 1:50 000 to 1:200 000. Although classified as a primary antibody deficiency syndrome, CVI represents a generalized state of immune dysregulation characterized by functional abnormalities of both T and B cells. Clinically, this is reflected in the susceptibility of these patients to a variety of conditions not easily explained on the basis of an isolated humoral immune defect.

Clinical features (Table 1)

Patients with CVI present with recurrent bacterial infections of the respiratory tract, such as sinusitis, otitis media, bronchitis and pneumonia. The most common etiologic agents are encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. The onset of these abnormally frequent infections may occur at any age but most patients do not come to medical attention until the second or third decade. This is in contrast to X-linked agammaglobulinemia, where recurrent infections develop in the first 2 years of life. The recurrent bacterial infec-

tions in CVI are a direct result of the deficiency in antibody production (specifically immunoglobulin G, IgG) that is the hallmark of this syndrome. If CVI goes undiagnosed (and hence untreated), recurrent pulmonary infections can lead to irreversible chronic lung disease with bronchiectasis. Septicemia and recurrent infections of the skin, urinary tract, joints or central nervous system also occur in patients with CVI, but are less frequent. In rare instances, patients with CVI can become infected with a variety of opportunistic fungi, mycobacteria and *Pneumocystis carinii*. An unusual syndrome of severe enteroviral meningoencephalitis is seen in patients with primary antibody-deficiency syndromes. This type of infection is most commonly associated with X-linked agammaglobulinemia, but several well-documented cases have occurred in patients with CVI. Other viral infections that can occur with increased frequency in CVI include recurrent attacks of herpes simplex and herpes zoster.

Patients with CVI suffer from a variety of infectious and noninfectious gastrointestinal disorders. The protozoan *Giardia lamblia* is a common cause of infectious diarrhea in these patients. Malabsorption, of unknown etiology, leading to severe weight loss and diarrhea, is another major gastrointestinal

Table 1 Clinical features of common variable immunodeficiency

Relative frequency	Recurrent infections		Autoimmune disease	Other
	Manifestation	Pathogens		
Most common	Sinusitis, otitis media, pneumonia	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	Hemolytic anemia Neutropenia, thrombocytopenia	Lymphadenopathy Splenomegaly Nodular lymphoid hyperplasia
	Infectious diarrhea	<i>Giardia lamblia</i> <i>Salmonella</i> spp. <i>Campylobacter</i> spp. <i>Cryptosporidium</i> Dysgonic fermentor-3	Pernicious anemia Autoimmune thyroid disease Rheumatoid arthritis Juvenile rheumatoid arthritis	Bronchiectasis
Less common	Septic arthritis	<i>Staphylococcus aureus</i> <i>Mycoplasma</i> spp. <i>Haemophilus influenzae</i>	Systemic lupus erythematosus Sjögren's syndrome Ulcerative colitis Crohn disease	Malignancy Cholelithiasis Idiopathic malabsorption Sarcoid-like granulomatous disease
	Meningitis	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Neisseria meningitidis</i>		
	Encephalitis	Enteroviruses		
	Pneumonia	<i>Pneumocystis carinii</i>		

manifestation of CVI. Small bowel biopsy reveals flattening of the villi with a lymphocytic infiltration in the lamina propria. Neoplasms of the gastrointestinal tract (specifically, adenocarcinoma of the stomach and intestinal lymphomas) appear to occur with increased frequency in CVI.

Approximately 25% of patients with CVI will develop one or more autoimmune diseases, indicating that CVI is a disease of abnormal immune regulation as well as immunodeficiency. Autoimmune (Coombs'-positive) hemolytic anemia and idiopathic thrombocytopenic purpura (ITP) are the two most common autoimmune diseases seen. Neutropenia is also seen in a significant number of patients with CVI, and in some cases antigranulocyte antibodies have been demonstrated. A variety of other autoimmune diseases can occur in association with CVI (Table 1).

Patients with CVI frequently develop lymphoproliferative disorders, which can take several forms. Malignant lymphoma occurs with increased frequency in these patients, although the exact magnitude of this increase is unclear. This high incidence of lymphomas (and cancers in general) is an indication that some patients with CVI may have clinically important defects in cell-mediated as well as humoral immunity. More common than malignant lymphoma is the occurrence of benign lymphoid hyperplasia manifested by one or more of the follow-

ing: splenomegaly; diffuse lymphadenopathy; or nodular lymphoid hyperplasia of the intestinal tract.

Immunogenetics

Evidence for a genetic influence was noted very early in the study of CVI, when family studies disclosed that a significant number of patients had first-degree relatives with other immunologic diseases such as isolated IgA deficiency and various autoimmune diseases. Recent studies have found an association of CVI and IgA deficiency with certain major histocompatibility complex (MHC) haplotypes. These results suggest that CVI and IgA deficiency are related disorders, susceptibility to which is determined by a gene or genes in or near the MHC region.

Immunologic features

The hallmark of CVI is a marked decrease in serum IgG, which is usually associated with significant depression of serum IgM and IgA levels. Despite this panhypogammaglobulinemia, the majority of patients with CVI have normal numbers of B cells in the circulation and peripheral lymphoid tissues. However, the numbers of surface IgG⁺ and IgA⁺ B cells are often reduced, suggesting an impaired ability of CVI B cells to undergo immunoglobulin class switching.

Although the exact nature of the immunologic defect(s) that give rise to CVI are unknown, a number of *in vitro* immunologic abnormalities have been identified in these patients. In early studies, peripheral blood lymphocytes from patients with CVI were stimulated *in vitro* with the lectin pokeweed mitogen, and culture supernatants were assayed for immunoglobulin production. A consistent finding in this type of study was the inability of peripheral blood lymphocytes from patients with CVI to secrete normal amounts of immunoglobulin. Since pokeweed mitogen-induced immunoglobulin secretion is strictly dependent on the presence of functional helper T cells, it was unclear whether this decreased immunoglobulin production by patient B cells was due to an abnormality intrinsic to the B cell or secondary to a T cell abnormality. In subsequent studies partially purified T cells and B cells of patients were separately analyzed in pokeweed mitogen-driven cultures containing allogeneic normal T cells and B cells. This approach showed that most patients with CVI appeared to have a B cell defect, in that coculture of their B cells with normal allogeneic T cells did not correct the defect in immunoglobulin production, and T cells from most patients were able to support immunoglobulin production by normal B cells. Occasional patients whose T cells were capable of suppressing normal B cell immunoglobulin production were identified, but in most patients shown to have excessive suppressor T cell activity, coculture of their B cells with normal T cells failed to rescue B cell function, thereby indicating that these patients also had a B cell defect.

More recent *in vitro* studies indicate that B cells from patients with CVI can be induced to proliferate and secrete immunoglobulin if appropriately stimulated. Studies using combinations of B cell mitogens or monoclonal antibodies (anti-CD40, anti-IgM) and various cytokines have shown that the severity of the defect in B cell immunoglobulin secretion varies among patients. In most cases B cells from patients with CVI can be induced to secrete at least some immunoglobulin; however, only a minority of patients produce normal amounts of all immunoglobulin isotypes. The *in vitro* defect in immunoglobulin secretion seen in CVI tends to be hierarchical, with IgM secretion affected least, IgG secretion affected to an intermediate degree, and IgA secretion reduced to the greatest extent. These results indicate that the B cell defect in CVI is not absolute and suggest that B cells from a subset of patients with CVI may only require the appropriate stimuli (which are presumably lacking *in vivo*) to mature into immunoglobulin-secreting plasma cells.

In addition to abnormalities of B cell function,

many patients with CVI also exhibit *in vitro* abnormalities of T cell function. In about half of CVI patients, a selective abnormality of T cell activation can be demonstrated; it appears to arise from a signaling defect and is manifest as reduced expression of genes directing the synthesis of interleukin 2 (IL-2), IL-4 and IL-5. In addition, T cells from a subset of CVI patients fail to express normal levels of CD40 ligand following activation. Since both CD40 ligand and lymphokines are essential ways by which T cells provide help to B cells for antibody secretion, the fundamental immunologic abnormality in some patients with CVI may be a defect in T cell help.

While most patients with CVI have a normal CD4:CD8 T cell ratio, approximately one-third of patients exhibit a reduced CD4:CD8 T cell ratio due to elevation in the absolute number of CD8 cells, most of which also express CD57 and HLA-DR. The expanded population of CD8 T cells in these patients have phenotypic and functional properties that are characteristic of activated cytotoxic T lymphocytes. The origin and functional significance of the expanded population of CD8 T cells in this subgroup of CVI patients is unclear.

Treatment

Standard therapy of CVI currently consists of intravenously administered immunoglobulin, which is less painful and more effective at preventing infections than intramuscular immunoglobulin. Vigorous treatment of infections and readiness to promptly evaluate and treat any unusual complications are also important aspects of managing these patients. Treatment of noninfectious complications is the same as in nonimmunodeficient patients.

COMPLEMENT, ALTERNATIVE PATHWAY

Peter J Lachmann, University of Cambridge, SmithKline Beecham Microbial Immunology Laboratory, Centre for Veterinary Science, Cambridge, UK

The term 'alternative pathway of complement activation' is used to describe the activation pathway that is alternative to the so-called 'classical' pathway of activation which was the model of complement activity used to characterize the system. The classical pathway is the reaction sequence by which antibody-sensitized sheep erythrocytes are lysed by human or guinea pig complement. It was already inherent in the original description of the third component of complement, by Coca in 1914, that there must be a separate pathway of complement activation used by yeast cell walls which depleted complement activity without depleting either C1 or C2. It was not until the 1950s, however, that Pillemer and his colleagues recognized that there was a novel pathway of complement activation which they described as the 'properdin pathway'. This pathway did not require antibody for its initiation and they postulated it to be a major mediating pathway for nonspecific immunity. They described a new protein – 'properdin' – which they ascribed the central role in this pathway and major importance in resistance to infection and tumors. Towards the end of the 1950s this group also described the existence of other new factors that were needed for the inactivation of C3 by zymosan. Although much of this work later turned out to be essentially correct, it was much contested at the time, largely by RA Nelson (in 1958), and the existence of

the alternative pathway was not fully accepted until the discovery of sera genetically deficient in C2 and C4 in the 1960s. It was also at this time that the complement components were first isolated as proteins and as antigens so that the biochemistry of their interactions could be worked out. It was not until the 1970s, however, that the biochemistry and reaction pathway of the alternative pathway was clarified after a period of considerable confusion.

At the heart of the alternative pathway is the C3 feedback cycle (**Figure 1**). The primary large cleavage product of C3 is C3b, which combines in the presence of magnesium ions with factor B – the C2-like protein of the alternative pathway – to form a bimolecular complex, C3b,B. This acts as a substrate for factor D – the C1 analog of the alternative pathway – which cleaves a bond in factor B splitting off a fragment, Ba, and leaving the complex C3b,Bb. This is the 'C3'convertase' of the alternative pathway and is the homologous enzyme to C4b,2b; the C3-converterase of the classical pathway. Generating a C3 cleaving enzyme from C3b provides a positive feedback amplification loop, generating more C3b and consuming more factor B until one or other of these components is exhausted. Factor D is a single domain serum protease occurring in plasma in active form. It was a great surprise when it was recently discovered, following the cloning of the molecule,

Figure 1 C3b feedback and breakdown. (From Lachmann PJ and Hughes-Jones NC (1984) *Seminars in Immunopathology* 7: 143–162.)

that factor D is identical to a serine protease known as 'adipsin' which occurs in fat tissue and in nerves. The function of adipsin is unknown, but its levels are strikingly reduced in certain genetic forms of obesity and of diabetes.

The C3b feedback cycle is subject to homeostatic control by an analogous reaction cycle where C3b combines with another normal serum protein – factor H – to give a complex C3b,H which is cleaved by another serine protease present in active form in plasma – factor I. Factor I cleaves two bonds in C3b, cleaving out a small fragment – C3f – and leaving the large fragment iC3b which still has important functions as an inflammatory mediator but is no longer capable of combining with factor B or giving rise to a C3 convertase. The rate of C3 activation by the alternative pathway is controlled by the relative velocities of the C3b feedback cycle on the one hand and the C3b breakdown cycle on the other.

The alternative pathway is therefore fired by any mechanism which either increases the rate of C3b production or reduces the rate of C3b breakdown. Mechanisms that increase C3b production include:

1. *The generation of extrinsic enzymes that cleave C3.* The principal of these is the C3-convertase of the classical complement pathway, C4b,2b. Kallikrein and plasmin also split C3 as does elastase and a number of proteases from phagocytic cells or from bacteria. At inflammatory sites a number of these enzymatic systems may be active.
2. *Mechanisms that stabilize the alternative pathway C3 convertase.* Physiologically this enzyme is stabilized by properdin which binds to it. This is the part that properdin plays in the alternative pathway – not at all what the Pillemer group had envisaged. Although properdin levels have not

been found of great diagnostic value, the total absence of properdin leads to (usually severe) immunodeficiency. A more complete stabilization of C3b,Bb is produced by autoantibodies that react with it. Such autoantibodies are called 'nephritic factors' since they were first described in mesangiocapillary glomerulonephritis. However, the renal disease follows the formation of the nephritic factors rather than causing it and the mechanisms underlying the formation of the nephritic factor remain unknown.

An artefactual way of producing a stable C3-convertase is the use of cobra venom factor. This is a reptilian analog of a C3 breakdown product that functionally resembles C3b and has the curious property that it combines with mammalian factor B but is not dissociated by mammalian factor H and therefore produces a stable C3-convertase not susceptible to homeostatic control which causes the C3b feedback cycle to run to exhaustion.

The principal mechanism that decreases the rate of C3b breakdown is the 'protected surface' phenomenon; C3b bound on certain surfaces is relatively poorly reactive with factor H and therefore resistant to breakdown whilst supporting the C3b feedback cycle by reaction with factor B. Such protected surfaces include particulate polysaccharides (for example zymosan and particulate inulin); the surfaces of most parasites and of many virus-infected and some tumor cells; and certain immunoglobulin aggregates particularly those of IgA. More dramatic failure of C3b breakdown occurs in the genetic deficiencies of factor I or of factor H. A further mechanism of reducing C3b breakdown is provided by local removal of factor H. This was first described for 'sulfated sephadex' and has been seen also with an intestinal glycoprotein and a myeloma light chain dimer. The physiological or pathophysiological relevance of this mechanism is still unclear.

The view that the alternative pathway is essentially governed by the velocity of competing reactions requires that there is a minimal level of C3b (or of a C3b-like protein) always available. This is the essential feature of the 'tickover' model of the alternative pathway. It was originally proposed that the tickover was maintained by minimal levels of proteolysis of C3 by any of the enzymes that can cleave it and indeed this is likely to be the case. However, another mechanism has been suggested: namely that the hydrolysis by water of the internal thioester bond generates a C3b-like molecule and that this spontaneous hydrolysis of C3 may be sufficient to keep the tickover working. The levels of C3b or C3b-like proteins that are required for the maintenance of the

tickover are so low that it has not so far been possible to define critically the relative roles of proteolysis and thioester hydrolysis in maintaining the tickover *in vivo*.

COMPLEMENT, CLASSICAL PATHWAY

Robert B Sim, MRC Immunochemistry Unit and Department of Biochemistry, University of Oxford, Oxford, UK

The complement system consists in total of about 20 soluble proteins in plasma and other body fluids, and a similar number of cell surface receptors and control proteins, present on blood cells and other tissues. Complement has a major role in controlling the uptake and removal, by phagocytosis, of materials such as immune complexes, microorganisms or host cell breakdown products, which are recognized by, and activate the system. Complement proteins, and their fragments generated during activation, also have roles in regulating cellular immune responses. Individual complement proteins serve the functions of recognizing and binding to target material. Recognition is followed by activation of serine proteases of the complement system (Figure 1), which assemble on the surface of the target. One such protease is termed C3 convertase and is capable of cleaving the most abundant soluble complement protein, C3. C3 is then cleaved and activated, and a major fragment of C3, called C3b, binds covalently to the target. Covalent binding occurs by direct nucleophilic attack of surface hydroxyl or amine groups of the target on an activated thioester within C3b. Surface-bound molecules of C3b, or of its proteolytic breakdown product iC3b, serve as ligands for C3 receptors on phagocytic cells, and so act as labels for phagocytosis

of the target. Surface-bound C3b also forms part of the binding site for C5, which is cleaved by the same protease which cleaved C3. The proteolytic fragment C5b binds to C6, C7, C8 and C9 to form the membrane attack complex, which, if the target material contains a lipid bilayer, associates with the membrane and may cause cell lysis.

The activation of the complement system occurs by either or both of two distinct routes (Figure 1). The first route for which the sequence of reactions was elucidated was termed the *classical pathway*, which consists of the proteins (or 'components') C1, C2, C4 and C3 (named in order of their sequence of action, which by historical accident, differs from numerical order). C1 is a large complex made up of three distinct proteins (or 'subcomponents') called C1q, C1r and C1s. A more recently elucidated route is called the *alternative pathway*, and consists of the proteins factor B, factor D and C3, together with the regulator proteins factor H, factor I and properdin.

Both pathways contain a target recognition mechanism, and both pathways lead to assembly of proteases which cleave C3 and C5. Cleavage of C5 by either pathway results in activation of the lytic pathway (components C5–C9). In the last few years, it has been shown that another protein similar in shape

Figure 1 Pathways of the complement system. The major stages of target recognition, protease activation, opsonization by deposition of C3b, and cell lysis are shown. Interactions of the classical pathway components are discussed in the text. The 'C3 convertase enzymes', C4b2a and C3bBb are shown prominently.

to C1q can also participate in classical pathway activation. This is mannose-binding lectin (MBL), a member of the collectin protein family. MBL appears to be associated with two proteases, named MASP-1 and MASP-2, which are homologous to C1r and C1s, and appear to have similar function. In some publications, activation of complement via MBL is regarded as a third, separate pathway (the lectin pathway), but it is discussed here as a 'branch' of the classical pathway. Discussion of the classical pathway thus is limited to the interactions of C1, C2, C4 and C3, MBL and the MASPs, together with 1) the soluble regulatory proteins C1-inhibitor, C4b-binding protein (C4bp) and factor I, which control activation of this part of the complement system, and 2) the cell surface receptors or regulatory proteins which interact with classical pathway components. These include complement receptor type 1 (CR1), membrane cofactor protein (MCP), decay-accelerating factor (DAF) and C1q receptor (C1q-R).

Distinction between classical and alternative pathways

In experimental work, the two pathways of activation can be readily distinguished, in that both pathways require Mg^{2+} , but only the classical pathway requires Ca^{2+} ions: if these are chelated by EGTA (ethyleneglycol-bis-(β -amino-ethylether) tetra-acetic acid) and Mg^{2+} ions are added in excess, only the alternative pathway will function. Further, the activation of the alternative pathway is prevented by dilution of human serum beyond about ten-fold, and is generally considerably impaired after 2–3 days storage of human serum at 4°C: the classical pathway, via C1q, operates at lower concentrations of serum and is stabler on storage. The stability of

activation occurring via MBL has not been extensively examined.

The proteins of the classical pathway and their mechanisms of action

C1

C1 is a multimeric protein consisting of two molecules each of the serine protease proenzymes C1r and C1s bound to a single molecule of C1q. The associations of C1q, C1r and C1s are the Ca^{2+} ion-dependent stages of the pathway. C1q itself consists of 18 polypeptide chains, of three different types, A, B and C, which are encoded by separate, closely linked genes on the short arm of human chromosome 1. The A, B and C chains are each about 225 amino acids long, and are homologous to each other. Each consists of a short N-terminal region containing a cysteine residue, followed by a stretch of 81 amino acids of collagenous sequence (i.e. repeating triplets of sequence Gly-X-Y, where Y is often a hydroxylated proline or lysine residue). The rest of the sequence is noncollagenous. The collagenous regions of one A, one B and one C chain align to form a short stretch of collagen triple helix structure, and the rest of the three chains fold to form a globular head, which consists of three lobes, one derived from each of the A, B and C chains (Figure 2). The collagenous stalk is bent in the middle, because of irregularities in the collagenous sequences. Fully assembled C1q (Figure 2) has a single cylindrical core, made up of the N-terminal ends of the six collagen triple helices: at the bend in the middle of the helices, they splay apart, forming six stalks, which join the six globular heads to the core. The overall appearance of C1q is likened to a bunch of six tulips. The globular head regions of C1q are responsible for recognition and binding to most classical pathway activators,

Figure 2 The assembly of C1q from three types of polypeptide chains. The assembly is discussed in the text. MBL has similar structure and assembly, but only one type of polypeptide chain.

while the collagenous regions interact with the next complement proteins in the pathway, C1r and C1s.

C1r and C1s are serine protease proenzymes, encoded by closely linked genes on human chromosome 12p13. Each monomer consists of a single polypeptide chain of about 700 amino acids: the C-terminal approximately 250 amino acids in each is a serine protease domain, homologous to trypsin or chymotrypsin. Like most complement proteins, they are mosaic proteins, i.e. segments of the primary sequence can be recognized as being homologous to segments of many other proteins, and are likely to represent independently folding domains or modules. The approximately 450 N-terminal amino acids of C1r and C1s are homologous to each other, and are made up of five domains (see Figure 3). Each con-

Figure 3 The modular structure of C1r, C1s, C2 and factor I. MASP-1 and MASP-2 have the same modules as C1r and C1s. (This diagram is adapted from the work of Dr A. J. Day.)

tains an EGF (epidermal growth factor) module, which is the Ca^{2+} -binding site. Each also contains two internal repeats of about 100 amino acids, known as CUB (C1r/C1s, Uefg, Bmp1) modules, and two CCP (complement control protein) modules, each about 60 amino acids long. CCP molecules are found in many complement proteins, and are a particular feature of the proteins which interact with C3 and C4 turnover, such as factor H, C4bp, CR1, MCP and DAF. The CUB domains are likely to be involved in binding to C1q.

The overall structure of each C1r or C1s monomer is a dumb-bell shape, with two globular regions of unequal size connected by a short strand. Isolated C1r exists as an elongated dimer, with the dumb-bells joined end-to-end. Two molecules of C1s bind, one to each end of the C1r dimer, in the presence of Ca^{2+} ions. This forms the very elongated C1r₂C1s₂ tetramer, which binds to the collagenous regions of C1q. The structure of the large C1 complex is not clearly established, but several models which indicate how C1r₂C1s₂ might interact with C1q have been proposed (see Colomb *et al.*, 1989 for review).

Activation of C1 occurs when two or more globular heads of C1q bind to a complement activator: movement of the heads is transmitted by the collagenous stalks to the core region and thence to C1r. A conformational change is induced in C1r, which causes the C1r molecules to cleave and activate each other: these then cleave and activate the C1s molecules. During this process, each C1r and C1s monomer is cleaved at the N-terminal end of the serine protease domain, forming a structure with two disulfide-linked polypeptide chains of approximately 56 and 28 kDa. The activated forms have very restricted proteolytic activity: activated C1r will cleave only proenzymic C1s, and activated C1s will cleave only C2 and C4. Both proteases have arginyl specificity. Both also have a low level of esterase activity towards esters of basic (C1r) or basic and hydrophobic (C1s) amino acids. In older literature, activated C1s is often described as C1 esterase, and the nomenclature C1r, C1s, and occasionally C1r₂, C1s₂ denoting the activated forms, is also frequently encountered.

C4

Once C1s has been activated, it will cleave and activate C4. C4 is a 205 kDa protein, synthesized as a single polypeptide chain, but processed on secretion into a form with three disulfide-linked polypeptides, named α , β and γ (97, 75 and 33 kDa). C4 is homologous to C3 and C5, and also to the family of protease inhibitors related to α_2 -macroglobulin. This group of proteins do not have an obvious mosaic

structure, and little can be predicted of their tertiary structure. Low-resolution analysis, by S.J. Perkins and colleagues, of the structure of C4 or C3 in solution, show that they are flat, ellipsoid molecules, about 18 nm long and 10 nm wide. C4, like C3, contains an internal thiolester in the α chain, formed between the Cys and Gln residues of a sequence Gly-Cys-Gly-Glu-Gln.

Activated C1s cleaves a 9 kDa fragment, C4a, from the N-terminus of the α chain of C4. C4a has weak anaphylatoxin activity. The rest of the molecule, C4b, contains the thiolester, which becomes exposed on proteolytic cleavage. The thiolester is very reactive, and will be attacked by any nucleophilic (electron-donating) species in the vicinity. Since C4 is normally activated by C1s which is within C1 bound to a complement activator, the reactive C4b (often called nascent C4b) is generated close to the surface of the activator, and can react with surface OH, NH₂ or SH groups. These form ester or amide linkages to the carbonyl group of the thiolester, and the carbon-sulfur bond in the thiolester is broken, forming a free SH group on the C4b (Figure 4). In this way, C4b becomes covalently bound to the surface of the complement activator. Much of the nascent C4b generated, however, simply reacts with the most abundant nucleophile present, water, and does not become surface-bound. This species, in which the thiolester is hydrolysed, plays no further part in complement activation.

Figure 4 The activation of C4, and covalent binding of C4b. C4 contains an internal thiolester which becomes exposed on cleavage of C4 by activated C1s. The exposed thiolester may react with OH or NH₂ groups on the surface of the complement activator (i) and (ii) or may simply react with water (iii). The activation and binding of C3 occurs in the same way.

The major histocompatibility complex (MHC) class III region of chromosome 6 contains two functional genes for C4: these encode the C4A and C4B isotypes of C4. The sequences of C4A and C4B differ by less than 1%, and both function as C4 in the complement system. They have differences, however, in their covalent binding reaction: activated C4B binds with similar efficiency to hydroxyl and amino groups, while C4A reacts much more readily with amino groups. In a standard assay of complement activity, in which erythrocytes are lysed by complement, C4B is more active than C4A, probably because C4B binds more readily to the carbohydrate-rich red cell surface than does C4A. In contrast, C4A binds better than does C4B to immunoglobulin G (IgG) immune complexes containing nonglycosylated protein antigen.

The selectivity of covalent binding of C4A and C4B appears to be controlled mainly by an Asp (C4A) to His (C4B) amino acid interchange at position 1106 in the sequence. These residues, although not adjacent to the thiolester in the primary sequence, are close in the tertiary structure, and affect polarization of nucleophilic groups approaching the thiolester.

The C4A (acidic) and C4B (basic) nomenclature is based on electrophoretic mobility and corresponds to the older terms 'fast' and 'slow' (C4F, C4S). Each isotype of C4 has many allotypes, distinguishable by agarose electrophoresis, which are designated C4A1, C4A2, C4B1, C4B2, etc. Null alleles (termed C4AQO or C4BQO) at either C4 locus are relatively common. The A and B nomenclature must be carefully distinguished from the a and b nomenclature used to designate proteolytic fragments: terms such as C4Aa, C4Ab, used to denote the proteolytic fragments of the A isotype, are also encountered. C4 fragments bound to erythrocytes carry the Chido/Rodgers blood group. In general C4A allotypes carry the Rodgers blood group, while C4B carries Chido determinants.

C2

C2 is a serine protease proenzyme, which is highly homologous to factor B of the alternative pathway. Both proteins are encoded by genes in the MHC class III region of human chromosome 6, closely linked to the C4A and C4B genes. C2 and factor B are, like C1r and C1s, mosaic proteins (see Figure 3). The N-terminal portion of C2 is made up of three CCP modules, followed by a segment of about 200 amino acids which is homologous to structures in von Willebrand Factor (and also in complement receptor type 3, CR3), and is referred to as a vWF-A domain. This is followed by a serine protease domain. C2 is

cleaved by activated C1s at an arginyl bond situated between the third CCP module and the vWF domain. This creates two nondisulfide-linked fragments, C2b (34 kDa, from the N-terminus) and C2a (74 kDa, C-terminal). There is some confusion in C2 fragment nomenclature, and the term C2a was sometimes used for the smaller fragment. Although C2 can be cleaved by isolated, activated C1s in solution, the C2 fragments produced have no proteolytic activity. To be active, C2 must form a complex with C4b before it is activated. During normal complement activation, C1s, within C1, bound to an activator, will cleave several molecules of C4, some of which will bind covalently to the activator. These can then bind C2, but in only a very few of the C4b–C2 complexes will the C2 be in an appropriate position to be activated by the surface-bound C1s. This may occur, for example, when C1 is fixed to the IgG Fc in an immune complex, and the C4b is fixed to the Fab arms. C2 associates first with C4b via the CCP-domain region at the N-terminus: this is Mg^{2+} -dependent. Cleavage of C2 by C1s then occurs, and the C2a portion remains bound to C4b by a secondary non- Mg^{2+} -dependent interaction, probably through the vWF-A domain. The complex C4b–C2a (generally written C4b2a) is proteolytically active, and is the C3 convertase enzyme of the classical pathway. The proteolytic active site is the serine protease domain of C2a. Proteolytic specificity is restricted to cleavage of single arginyl bonds in C3 and C5. Activated C2, whether free in solution or bound to C4b, has a very low level of esterolytic and amidolytic activity.

C3

C3, as noted above, is homologous to C4: it is a major component of the alternative, as well as the classical pathway. C3 is synthesized as a single polypeptide chain, and processed on secretion into two disulfide-linked chains, α (110 kDa) and β (75 kDa). C3 is cleaved and activated by C4b2a (or by the alternative pathway C3 convertase, C3bBb). Cleavage releases the anaphylatoxic fragment C3a (77 amino acids) from the N-terminus of the α chain. The rest of the molecule, C3b, has like C4b (Figure 4), an exposed reactive thiolester, and will react with surface hydroxyl or amine groups on the complement activator, or with water. Covalent binding to an activator is called the 'acceptor binding reaction' of C3b to distinguish it from noncovalent binding to specific receptors. Again only about 10% of the 'nascent' C3b generated binds to the activator: the rest reacts with water and diffuses away. The half-life of the reactive thiolester is $<100 \mu s$, and so nascent C3b can diffuse only a short distance before

it reacts with a nucleophile. The surface-bound C3b is therefore clustered around the site of proteolytic activation: such clusters are likely to be important in promoting adhesion to C3 receptors. Among the C3b molecules which become activated, one may become bound to the C4b portion of the activating enzyme. This forms a C4b2a3b complex. The covalently associated C4b and C3b molecules form a binding site for C5, which orients C5 for cleavage by the protease domain of C2a, thus initiating the lytic phase of the complement system. C4b2a3b is referred to as the C5 convertase of the classical pathway.

The lectin pathway

Recent work has shown that a protein similar in structure to C1q, mannan- or mannose-binding lectin (MBL), can substitute for C1q in the activation of complement. MBL was formerly called mannose- or mannan-binding protein (MBP) or Ra-reactive factor (RaRF). MBL is made up of 18 identical polypeptide chains, which like those of C1q, contain an N-terminal collagenous segment, and a C-terminal noncollagenous region. The chains associate in groups of three to form collagen triple helices, and six of these groups associate to form the whole molecule (as shown for C1q in Figure 2). MBL, like C1q, has a collagenous core and stalks, and three-lobed globular heads. The major difference from C1q is that the MBL globular heads are lectins, and bind to carbohydrate in the presence of calcium ions. MBL binds mainly to mannose-rich structures, such as yeast mannan. MBL is thought to occur in forms with three, four, or five globular heads instead of six, but this may be an artefact of purification. *In vitro*, MBL bound to a target such as mannan binds and activates $C1r_2C1s_2$, and so activates the complement classical pathway. Other evidence strongly suggests however that *in vivo* MBL is associated with other proteases. One of these, MASP (MBL-associated serine protease) or MASP-1 is known to form a complex with MBL, and is highly homologous to C1r and C1s. Another highly homologous protease MASP-2 has been characterized by cDNA sequencing, and appears also to be involved in complex formation with MBL. The activities of MASP-1, and particularly MASP-2 are not yet known in detail. However MASPs can cleave and activate C2 and C4, and are thought also to cleave C3 at a low rate. MBL therefore probably mediates activation of the classical pathway via the MASPs. In density-gradient centrifugation of plasma, MBL sediments as a 19S complex, of the same size as the C1 ($C1qr_2s_2$) complex. C1q or MBL which are not associated with proteases migrate as 11S proteins. This indicates that MBL

forms a complex like C1 in plasma. This is probably an MBL–MASP complex, although formation of MBL–C1_{r2s2} complexes might also be possible. This MBL complex has previously been characterized under another name, Ra-reactive factor (RaRF) which has been identified in sera from several vertebrates, particularly rodents. RaRF was detected by its binding to the Ra polysaccharide found on enterobacteria, e.g. *Salmonella*, and was shown to consist of MBL and a serine protease (presumably corresponding to MASP-1, or possibly MASP-1 and -2) which activates C2 and C4.

Activators of the classical pathway

The classical pathway is activated, via C1q or MBL, by a wide range of materials. Both C1q and MBL mediate antibody-dependent and nonantibody-dependent activation. These are summarized in Table 1. For C1q, activators include immune complexes containing IgG or IgM, or *in vitro*, aggregated IgG. Human subclasses IgG3 and IgG1 are more efficient activators than IgG2 and IgG4. Interaction with IgG is via the C_γ2 domain, and protein engineering studies by Winter and Duncan indicate that charged residues Glu318, Lys320 and Lys322 in IgG are of major importance in C1q binding. In IgM, the C_μ3 domain is implicated in C1q binding. MBL binds to glycosylation variants of IgG (IgG

lacking terminal galactose residues on the Fc oligosaccharides), and activates complement. MBL also interacts with high-mannose oligosaccharides on IgM, although it is not known whether this interaction does lead to complement activation.

A wide range of gram-negative bacteria have been reported to bind C1q directly, and activate C1, without need for antibody. Mycoplasma species may also activate C1, as do some viruses, including Epstein–Barr virus and Rauscher leukemia virus, and some parasites, such as *Entamoeba*. Many bacteria, viruses and single-cell or multicellular parasites activate complement without need for antibody: alternative pathway activation is the commoner mechanism, but in many cases the contribution of the classical pathway has not been fully studied. Yeasts activate the classical pathway via MBL, as well as activating the alternative pathway. MBL also binds to saccharides on a wide range of bacteria, viruses and fungi, but complement activation via MBL has not generally been examined in these systems.

Tissue-damage products, such as mitochondrial and other subcellular membranes, cytoplasmic filaments, polynucleotides and components of myelin have also been reported to activate C1. The acute phase protein CRP (C-reactive protein), when bound to phosphorylcholine-containing phospholipids, binds and activates C1. Since C1q recognizes a very wide range of targets, mostly via its globular heads,

Table 1 Classical pathway activators

The classical pathway is mainly involved in recognizing charge groupings. This is the case for C1q and CRP, but not for MBL which recognizes neutral sugars. Charges may be on proteins, like IgG, or on complex charged carbohydrates found on surfaces of microorganisms, or on nucleic acid–protein complexes, or on lipids and glycolipids. Sialic acid on cell surfaces tends to promote activation of the classical pathway, but to inhibit activation of the alternative pathway.

Classical pathway activation occurs via:

C1q:	C1q binds to: - Fc portions of antigen-fixed IgG and IgM - Nucleic acid and chromatin - Cytoplasmic intermediate filaments (vimentin-type) - Mitochondrial membranes possibly via cardiolipin or via mitochondrial proteins - Some viruses, e.g. MuLV - Gram-positive bacteria, e.g. some pneumococci, streptococci, via capsular polysaccharide (neuraminidase treatment reduces activating capacity) - Gram-negative bacteria via the lipid A component of the lipopolysaccharide of the cell wall
CRP + C1q:	CRP (C-reactive protein) recognizes phosphate groups in choline phosphate of pneumococcal C-type polysaccharide, and also binds to phosphocholine (PC)-containing and non-PC-containing microbial polysaccharides and lipids, polyanion/polycation complexes, and chromatin. It is also reported to bind to galactans. Bound CRP interacts with C1q, and activates the classical pathway
Mannose-binding lectin (MBL):	MBL binds to high mannose and other polysaccharides and oligosaccharides on yeasts, bacteria and viruses, and activates the classical pathway. It also binds to carbohydrate on glycosylation variants of IgG (IgG-Go). MBL probably acts, <i>in vivo</i>, via the proteases known as MASPs, but <i>in vitro</i> it can act via C1r and C1s. RaRF, formerly reported as being a specific factor mediating classical pathway activation by <i>Salmonella</i> Ra polysaccharide, is the same as MBL.

it is likely that the three homologous 'lobes' of each head have different binding specificities, but this has not yet been proved.

The quantitative significance of complement activation via MBL is not yet clear. MBL and the MASPs are at very low concentration in plasma relative to C1q, C1r and C1s (see Table 2).

Control mechanisms

The activation of the classical pathway has multiple control mechanisms. The proteolytic activity of activated C1 is controlled by C1-inh, which irreversibly activates C1r and C1s. It is also a physiological inhibitor of kallikrein and activated factors XII and XI. C1-inh is a 100–110 kDa single polypeptide chain protein, containing about 50% carbohydrate. It is homologous to other serpins, such as antithrombin III. It acts as a pseudosubstrate for the proteases which it inhibits: these cleave an Arg–Thr bond 34 residues from the C-terminus of C1-inh, but C1-inh remains covalently bound to the protease, probably by an ester bond formed by the arginine carbonyl and the active-site serine of the protease. C1-inh attacks activated C1 by first reacting with C1s, then with C1r: the C1r₂C1s₂ complex dissociates to form two C1inh–C1r–C1s–C1inh complexes, which no longer bind to C1q. C1q, still bound to the complement activator, can now bind to C1q receptor, or can participate in a further slow cycle of binding, activation and inactivation of C1r₂C1s₂. MASP-1 is

also inhibited by C1-inh, but this has not been investigated for MASP-2.

The C3 and C5 convertase enzymes are also subject to control: one aspect of control is the inefficiency of binding of nascent C4b and C3b to appropriate sites to form the convertases. Once formed, the convertases are unstable: C2a dissociates from C4b or C4b3b with a half-life of 2–5 min. Once C2a has dissociated, more C2 can bind to C4b, but the adjacent C1 molecule required to cleave the C2 may already have been inactivated. The stability of the convertases is further decreased by a group of control proteins which includes the plasma proteins factor H and C4bp, and the membrane proteins CR1, MCP and DAF. These proteins, together with CR2, are composed mainly, or only of CCP domains, and are all encoded by genes in the RCA (regulation of complement activation) cluster on human chromosome 1q31–32.

CR1, DAF and C4bp bind to C4b2a or C4b2a3b and cause C2 to dissociate: they also compete with C2 for the initial binding to C4b. CR1 and C4bp, and also MCP, once bound to C4b, render C4b susceptible to attack by the control serine protease, factor I, which cleaves at two sites in the α chain of C4b, forming C4c (145 kDa) and C4d (45 kDa), which no longer participate in convertase formation. CR1 and MCP also act as cofactors for the factor I-mediated cleavage of C3b to form iC3b, as does factor H. In the alternative pathway, CR1, DAF and factor H accelerate the decay of the C3 convertase,

Table 2 Properties of classical pathway proteins

Protein	Mol. wt (kDa)	Chromosomal localization of gene	Plasma concentration ($\mu\text{g ml}^{-1}$)
<i>Components</i>			
C1q	462	1	80
C1r	83	12	50
C1s	83	12	50
C4	205	6	600
C2	102	6	20
C3	185	19	1300
MBL	500	10	<1
MASPs	80–90	?	<1
<i>Regulatory proteins</i>

<i>Membrane proteins</i>			
CR1	160–250	1	<i>Distribution on blood cells</i> Erythrocytes, polymorphs, monocytes, B lymphocytes
MCP	45–70	1	B and T lymphocytes, monocytes, polymorphs
DAF	70	1	Erythrocytes, leukocytes and many other tissues
C1q-R	60	?	B and T lymphocytes, monocytes, polymorphs

C3bBb, by displacing Bb, and by competing with factor B for binding to C3b.

Receptors and classical pathway components

C3b and its breakdown products, iC3b, C3dg and C3d, bind to several receptors, including CR1, CR2 and CR3: these are discussed in more detail elsewhere. C4b binds to CR1, and immune adherence to erythrocytes can be mediated by a CR1–C4b interaction, rather than by CR1–C3b. During normal complement activation, much more C3b is fixed than C4b, and it is unlikely that C4b has an important role in receptor-mediated adhesion or ingestion mechanisms. C1q also binds, via its collagenous region, to a receptor, a widely distributed 60 kDa species (C1q-R). C1q-R also binds other ligands (collectins) which are structurally similar to C1q: these include MBL, lung surfactant protein A and conglutinin. All of these ligands are reported to function as opsonins, and a major role of C1q-R may be a phagocytic uptake.

Pathological alterations of the classical pathway

The functioning of the classical pathway is disrupted in many circumstances. These include genetic deficiencies of single components: complete deficiencies of C1q, C1r, C1s, C4, C2, C3, factors H and I have been reported. These are associated with susceptibility to infection and/or inappropriate deposition of immune complexes. Low concentrations of MBL are associated with poor opsonization of yeast and some bacteria, and with recurrent infection in infants. Diminished synthesis of C1-inh, or synthesis of inactive C1-inh mutants is the cause of hereditary angioedema, and causes secondary consumption of C2 and C4. Autoantibodies to C1-inh have been reported, which destabilize the C1-inh-protease complex releasing free active protease: these give rise to autoimmune angioedema. Autoantibodies to C3 convertases, termed nephritic factors, occur in membranoproliferative glomerulonephritis. These generally recognize C3bBb, but a few reports indicate reactivity against C4b2a. They stabilize convertases, leading to excessive consumption of C3. Autoantibodies against bound C1q occur in systemic lupus erythematosus (SLE), but it is not clear to what extent they affect the function of C1q.

Further effects on the classical pathway arise from the presence of reactive thioesters in C3 and C4: the thioesters can be cleaved by low molecular weight nucleophiles without the need for proteolytic ac-

tivation of C3 or C4: this occurs at a low rate with water, causing hydrolysis of the thioester and generating species named C4(H₂O), C4u or C4b-like C4 (and similarly for C3). Ammonia production in ischemic tissue, or during kidney malfunction, may cause extensive formation of these species. C3b-like C3 can bind factor B, and cause alternative pathway activation; formation of C4b-like C4 does not cause further complement activation.

Activated (nascent) C4b and C3b, as well as reacting with water or binding to complement activator surfaces, will react with any strong nucleophile present; any such species will inhibit the binding of C3b and C4b to its real target, the complement activator. A number of drugs which are nucleophilic or have nucleophilic metabolites induce SLE as a toxic side-effect, and these may act by inhibiting C4b and C3b binding, diminishing the opsonization of immune complexes.

COMPLEMENT DEFICIENCIES

Klaus O Rother and Ursula A Rother, Institute of Immunology, University of Heidelberg, Germany

Inherited deficiencies of all known complement (C) components, of most regulator proteins and of the respective receptors have been found in humans. Table 1 is a compilation of the defects. Although acquired deficiencies – be they by consumption or otherwise – may also cause clinical conditions comparable to those listed in Table 1, they will not be specifically addressed in this entry.

Inherited deficiencies are rare. Since complement is not routinely measured in healthy persons, the incidence is difficult to determine and so is the disease incidence in a given component deficiency. In a Japanese study of healthy blood donors, C5, C6, C7 and C8 have each been found missing in about 3 per 100 000. C9 was absent in 3 per 1000. The prevalence of deficiencies of the late-acting components together was calculated at approximately 12 per 100 000. Some combined deficiencies – total or sub-total – of two or more components were reported when the terminal complex was afflicted. Deficiency in C7 in some cases was combined with the additional absence of C4 (C4a and/or C4b).

Considering the many biological activities associated with complement activation (Figure 1), it initially came as a surprise that clinical symptoms were absent in many cases of missing components. However, experimentation with defective animals clarified the situation by showing that redundant pathways are operative to assure complement-dependent life-preserving functions. Thus, a missing link in one pathway may cause defect symptoms only if other pathways are also affected, or if control of a given condition requires mobilization of all reserves.

By and large, the syndromes expected in complement-deficient states may be subdivided into three groups.

1. Recurrent and/or persistent infections

Bacteria may cause life-threatening conditions in the absence of C3 or factor I or any part of the alternative pathway. Since absence of factor I results in total consumption of C3, the outcome in functional terms is identical with a primary lack of C3. Opsonization and phagocytosis are drastically diminished in these conditions. A contributory factor in combined deficiencies may be a defective immune response, as shown in C4-, C2- and C3-deficient states.

Deficiencies of the later reacting components C5, C6, C7 or C8 are often associated with infections, almost exclusively with meningococci or gonococci, suggesting that the normal defense against these strains rests mainly with the bactericidal (membrane attack) function of complement. In this light, the apparent health of the C9-deficient individuals may be explained with the intact membrane attack function of C5b678 in the absence of C9, although proceeding somewhat more slowly.

2. Connective tissue or immune complex diseases

Most striking is the association of unclear nature of systemic lupus or other autoimmune conditions with C1qrs, C4 or C2 defects alone or in combination with other factor defects. It is surmised that the pathophysiology in these disease states is a defect in

Figure 1 Reaction pathways of complement and biological activities. ----▶, Inhibition; a.p., alternative pathway; C1 INH, C1 inhibitor; IC, immune complexes; B, factor B; D, factor D; H, factor H; I, factor I; DAF, decay-accelerating factor; MAC, membrane attack complex; P, properdin; TCC, terminal complement complex (see article entitled Complement, Classical Pathway for further clarification).

complement-dependent clearance or solubilization of immune complexes due to a failure to enhance the feedback loop in alternative pathway activation.

One of the most common abnormalities involves the C1 inactivator which regulates the classical pathway as well as the kinin and clotting systems. It is this threefold intervention that has so far prevented a clear-cut opinion on whether the symptoms of hereditary angioedema (HANE) are causally related to the complement or to the other two systems. The defect is, so far, the only one in which the infusion of the missing factor ameliorates the clinical condition.

Little is known of receptor deficiencies, except for a decreased expression of receptor molecules such as

CR1 – whether inherited or acquired – in certain immune complex diseases. It seems reasonable to predict a pathogenic role for the lack of the receptors, as CR1 not only serves as a cofactor for factor I (Figure 1) but is also the main receptor molecule on the surface of erythrocytes used to transport immune complexes. A deficiency of CR3 has been described in a boy with severe infections.

Another cell surface constituent involved in complement regulation is the C8 binding protein (C8bp). It controls lysis of homologous cells. Along with other similar factors, C8bp (Table 1) is missing in paroxysmal nocturnal hemoglobinuria (PNH) cells, which are therefore abnormally sensitive to lysis by

Table 1 Inherited complement deficiencies in humans

Component	Inheritance	Remarks	Observed clinical condition	Laboratory findings
C1q	Autos. codom.	Three types: 1) partial, 2) complete, 3) inactive protein: combined with immunoglobulin deficiency	Infections, SLE	CH50 = 0 Bactericidal activity = 0 C1 $\uparrow$ C1s $\uparrow$
C1r, C1s	Autos. codom. not MHC linked	Mostly combined C1r + C1s	Infections (meningitis); Collagen diseases	CH50 = 0 C1 NH $\uparrow$
C4	Autos. codom. (4 genes) MHC linked	Degree dependent on number of 'null' alleles	Collagen diseases; some combined with IgA disorders	CH50 = 0; Bactericidal activity = 0; Chemotaxis $\downarrow$ Opsonization $\downarrow$: no IgM $\rightarrow$ IgG switch; MLC $\downarrow$
C2	Autos. codom. MHC (A25, B18, DR2) linked	30–70% activity in heterozygotes	Often none; Infections when combined with low factor B; SLE; juvenile rheumatoid arthritis	CH50 = 0 Bactericidal activity = 0 Phagocytosis $\downarrow$
C3	Autos. codom. not MHC linked		Severe infections; collagen diseases; nephritis	C3 < 0.1% CH50 = 0; bactericidal activity = 0; immune adherence = 0; opsonization $\downarrow$ Mobilization of PMN $\downarrow$ Factor B cleavage = 0 Chemotaxis $\downarrow$
C5	Autos. codom. not MHC linked (regulatory gene?)	13–65% activity in heterozygotes	Collagen diseases; Infections with meningococci, gonococci	CH50 = 0; bactericidal activity = 0; chemotaxis = 0 Platelet aggregation = 0 Opsonization normal (staphylococci)
C6	Autos. codom. not MHC linked; linked to C7 and C9 on chromosome 5		Gonococcal and meningococcal infections; streptococcal meningitis; chronic meningococcemia	CH50 = 0 Bactericidal activity = 0 Chemotaxis normal Opsonization and intracellular killing = normal Subtotal deficiency: truncated proteins hemolytically functional CH50 = 0; Reactive lysis positive; sera activatable up to C5,6
C7	Autos. codom. not MHC linked		Some healthy: 50% <i>Neisseria</i> infections: 12% connective tissue disorders	
C8	Autos. codom. not MHC linked C8 $\alpha\gamma$ and C8 β controlled by two independent loci	C8 $\alpha\gamma$ or C8 β missing; can be reconstituted with missing part; dysfunctional C8 β chain?	Meningococcal infections (often uncommon serogroups)	CH50 = 0
C9	Autos. codom. not MHC linked		None	Normal lysis and bactericidal activity at reduced rate (erythrocytes and <i>Escherichia coli</i>)

C1 NH	Autos. codom. structural gene	Three types: I) synthesis deficiency II) inactive protein III) C1 NH complexed to albumin (acquired deficiency sometimes by autoantibodies)	Angioedema following trauma or stress. Therapy: danazol, C1 NH infusion	C1 NH function↓ C1 NH protein↓/normal C4↓C2↓ C1↓ in acquired form
Factor I	?		Pyogenic infections, meningitis. Therapy: plasma infusion	CH50↓ C3↓ C3b↓ Factor B↓ properdin↓ Factor H↓ Bactericidal activity↓ Chemotaxis↓; phagocytosis↓ CH50↓ C3↓ factor B↓ C3d present on erythrocytes C5–C9 normal CH50 = normal Properdin = protein/0 apH50↓ Opsonization↓ CH50 normal during attacks: Histamine↑; C3a↑ C4↓; C3↓; Factor B cleavage
Factor H	Autos. recessive? codom.?	Low levels present	Hemolytic uremic syndrome; dense deposit disease; lupus nephritis	
Properdin	X-linked	1) Complete, or 2) partial Low titers present	Meningococcal meningitis; septicemia None (?) Chronic idiopathic urticaria/angioedema	
Anaphylatoxin inactivator (carboxypeptidase N)	Autos. recessive			
CR3 (CD18 deficiency)	Autos. codom.	Three proteins missing; relative contribution unclear	Recurrent infections, LAD	Proteins missing on leukocytes; zymosan response of monocytes↓
CR1	? Acquired?		Immune complex disease	Diminished CR1 on erythrocytes. Defective immune clearance
C8bp ('HRF')	Acquired	Reduced in PNH	Intravascular lysis	Acid lysis
C59 ('p18', 'MIRL' or 'HRF20')	Acquired	Reduced in PNH	Intravascular lysis	Acid lysis
DAF	Acquired	Reduced in PNH	Intravascular lysis	Acid lysis

homologous complement. Intravascular lysis is the clinical syndrome.

One of the enzymes regulating split-product activity of the effector phase is the anaphylatoxin (C5a) inactivator (carboxypeptidase N). It cleaves the terminal arginine off the C5a peptide, resulting in the C5a_{desarg} form. *In vitro* C5a_{desarg} has lost its spasmogenic and basophil-stimulating activities, as well as a large part of its chemotactic activities. *In vivo*, however, the chemotactic activity is not diminished by the loss of the arginine. The clinical role of the regulator defect is doubtful. One family with anaphylatoxin inactivator deficiency and HANE symptoms has been described.

With a few exceptions (see above) the therapy in complement-deficient conditions is symptomatic. A more direct approach such as gene therapy is untried.

3. Immune response

Antibody production following administration of limited amounts of antigen to mice was drastically reduced in the cobra venom factor-induced absence of C3 and this was true for both T cell dependent and T cell independent antigens. Both primary and secondary immune responses were affected by the treatment. Similarly, guinea pigs genetically deficient in C3 were poor responders in the primary phase and later failed in the switch to IgG. Analogous observations were made in C2-deficient guinea pigs or C4-defective mice. In mice with an inherited absence of C4, a fully functional immune response could be elicited following administration of C4. A boy deficient in C4 was analyzed for antibody production with similar results. Since C5-deficient mice were normal immune responders the impaired functions must be dependent on C3. This was further supported by studies on the role of the CR1 or CR2 receptors for C3 split products. Experimental blockade *in vivo* by monoclonal antibodies resulted in markedly reduced primary and secondary antibody responses to low concentrations of antigen. Memory formation was also diminished but T helper cells were not affected. As far as tested in these studies, larger amounts of antigen elicited undiminished responses. It is thus postulated that as yet unidentified enhancing functions are associated with C3 split products in the antigen-presenting pathways and that large-dose immunization does not need the enhancement.

Animal experimentation was the key tool in analyzing the biological functions of complement (Figure 1). While decomplementation (inactivation) of components by various means was helpful, the advent of strains with hereditary deficiencies provided more clearly defined conditions. Presently available are strains with a deficiency in C2 (guinea pigs), C4 (guinea pigs, including a coisogenic +/- colony), C3 (guinea pigs, dogs), C3a receptor (guinea pigs), C5 (mice, including a coisogenic +/- colony) or C6 (rats, pigs, rabbits). Genetic engineering to delete production of defined components is in progress. So far gene knockout mice with no C3 or factor B have been constructed. Further advances are expected from the production of recombinant species-compatible fluid phase inhibitors such as, for example, the CR1 receptor for C3. The trans-species genetic transfection of cell surface control factors may help in circumventing the otherwise effective complement attack against xenografts.

COMPLEMENT FIXATION TEST

Seppo Meri, Department of Bacteriology and Immunology, Haartman Institute, University of Helsinki, Helsinki, Finland

Carl-Henrik von Bonsdorff, Department of Virology, Haartman Institute, University of Helsinki, Helsinki, Finland

The complement fixation (CF) test has traditionally been used for the determination of antimicrobial (viral, bacterial, parasitic and fungal) antibodies in patient sera. In a broader sense, CF refers to any technique that exploits the binding and activation of complement components as a reporter system for antigen-antibody reactions. Potential applications thus include: 1) direct measurement of complement activity using antibody-sensitized erythrocytes; 2) indirect complement consumption assay to detect antibody or antigen; and 3) determination of complement-activating ('fixing') autoantibodies (such as islet cell antibodies in diabetes). Although the CF test could be considered as a piece of history of immunology transferred to the modern world, it still has a significant role in diagnostics and research in human and veterinary medicine. Despite the fact that the method represents a multicomponent biological assay with many easily disturbed components, it works well in professional hands. The method is thoroughly known, reliable, inexpensive in material costs and especially well suited for screening purposes. On the negative side are the long time it takes to obtain results and the labor intensity of the assay.

Principle of the test

The CF test is based on the ability of patient serum antibodies to form complement-activating immune complexes upon binding to their antigens. In immune complexes the complement component C1q binds to neighbouring Fc regions of antibody molecules with at least two of its six globular heads. In subsequent reactions some of the early complement components (C1s, C4, C2 and C3) are consumed in sequential proteolytic cleavages. The antibody assay (Figure 1) is performed in two stages: first, a dilution series of antibody (the serum to be studied) is mixed with a standard amount of antigen and complement (guinea pig serum is usually used as a source of complement components); second, a detection system for unconsumed complement (rabbit antibody-coated sheep erythrocytes, EA) is added. Lack of hemolysis in the detection system indicates the presence of antibodies. The test is quantitative and the result is usually given as the highest titer of patient serum that still prevents

lysis of the indicator cells. Critical components in the assay are the complement (fresh frozen or lyophilized guinea pig serum) and the sheep red blood cells (E). The latter requires the use of cells from a single or a couple of selected animals. The amount of antibody on E needs to be optimized to a saturating, but subagglutinating, level so that the assay is sensitive to changes in complement activity. The amount of complement is titrated to a level that typically corresponds to twice the amount of the 50% hemolytic dose (CH_{50}) under the test conditions. The amount of complement should be just enough to lyse the indicator cells. Controls for the viability of the detection system (EA + complement), background lysis (no complement) and 100% lysis (lysis by water) need to be included. Reproducibility of the CF assay requires that the ionic strength, pH, Ca^{2+} and Mg^{2+} content remain constant. Chelators (EDTA, EGTA) should not be used in the test samples because they directly block complement activity. As the test sera must be void of their own complement, they are heat-inactivated before the assay. For most applications the method utilizes 96-well microtiter plates; it can be automated. A detailed description of the standardization and procedure can be found from the further reading listed below.

Application and interpretation of the assay

The CF test is often used for the screening of antibodies against a variety of possible pathogenic microbes (especially viruses); for this a pool of 15–20 different antigens can be used. Most antigens are commercially available and reasonably priced. Relatively crude antigens (infected cell lysates) are mostly sufficient for the test. Test sera need to be screened in at least two dilutions because in high titer sera an excess of antibody may fail to generate complement-activating immune complexes (the "prozone" effect).

The test is relatively simple to perform and easy to interpret. The CF test broadly measures the humoral immune response (immunoglobulin M (IgM) and IgG class antibodies) against specific microbial antigens. A diagnosis of an acute infection can be made by demonstrating a significant increase in the anti-

Figure 1 Principle of the complement fixation test.

body titer against a given microbe in paired patient serum samples (generally taken 7–10 days apart from one another). A minimum of a fourfold increase (or sometimes decrease) in antibody level is diagnostic. In screening, a practical way of testing is to analyze the second serum sample at low dilutions (e.g. 1:8 and 1:16) with all the antigens in use and subsequently to test both sera at higher dilutions for the antigens which are positive. A high titer in a single serum sample can be indicative of the state of immunity against the microbe. A declining titer may be the sign of a somewhat older infection. Because of its relatively low sensitivity the complement fixation test may not be applicable for the demonstration of protective immunity acquired a long time ago. Other tests, such as ELISA, are more suitable for this purpose.

The use of the CF test is hindered if the patient serum sample turns out to be 'anticomplementary', i.e. it consumes complement from the test mixture without addition of antigen. The anticomplementarity is usually due to the presence of pre-existing complement-activating factors in the patient sera. These include immune complexes and other immune aggregates, cryoglobulins, contaminating bacteria or bacterial products such as endotoxin. For example, acute sera from patients with a parvovirus B19 infection often contain immune complexes and are anti-

complementary. Polyclonal B cell activation in patients with an Epstein-Barr virus infection may generate, for example, antibodies against sheep erythrocytes that also can give a false (positive) result in the assay. An additional control to exclude direct anticomplementarity of the test serum (test mixture in the absence of antigen) is thus essential.

COMPLEMENT, GENETICS

C Rittner and **PM Schneider**, Institute for Legal Medicine of Johannes Gutenberg, Universitaet Mainz, Mainz, Germany

In 1919, Moore discovered a strain of guinea pigs that was complement deficient; for example, serum of these animals did not mediate antibody-dependent cytolysis. Since that time substitution of a component either artificially depleted from or genetically deficient in sera of individuals of a given species has been a major tool of complement research. In humans, a number of autoimmune diseases have been associated with complement deficiencies of the classical pathway. Additionally, fulminant or recurrent bacterial infections are directly correlated with genetic deficiencies of early and late complement components, respectively. The first polymorphism of a complement component was found by Alper and Propp for the third component in humans in 1968. Subsequently, knowledge about deficiencies and polymorphisms in different species at the phenotypic and genotypic level has continuously accumulated.

Definition of genetics

Polymorphism was defined by Ford as 'the occurrence together in the same habitat of two or more discontinuous forms, or "phases", of a species in such portions that the rarest of them cannot be maintained by recurrent mutations'. Polymorphism of complement components can be studied at four different levels:

1. by allotyping of native complement components in serum (the phenotypic level);
2. by defining their subunit composition (the subphenotypic level);
3. by establishing the population and formal genetics (frequency of allotypes, and frequency and segregation of the respective genes/alleles);
4. by gene mapping and DNA sequencing to reveal the gene structure and define sequence variants (the genotypic level).

For this purpose, a complex methodology including electrophoretic and isofocusing techniques with functional or immunologic detection of individual

components, serology, quantitation, Southern blot and restriction fragment length polymorphism (RFLP) analysis, polymerase chain reaction (PCR) amplification and sequencing of DNA is applied (Table 1). By these means, insights into the evolution of polymorphisms and deficiencies and structure–function relationships, as well as into genetically determined disease susceptibilities, are gained. The analysis of complement polymorphisms at the DNA level has provided an even more complex picture by revealing further variants, which subdivide alleles defined at the protein level. DNA sequence analysis of protein allotypes of a number of complement components has demonstrated that most sequence variations are not confined to short stretches of genomic DNA, but rather are scattered throughout the entire gene; therefore it appears to be technically difficult completely to replace protein typing methods by direct DNA typing using the PCR methodology. A combination of typing methods, both at the protein and the DNA level, should be applied to obtain complete analysis for complement component polymorphisms, as well as for the detection of complement deficiencies.

Gene clusters of complement components and their function

In humans, most genes coding for complement components and related proteins have been cloned, partially or completely sequenced and assigned to chromosomal locations, providing further insight into the evolutionary origin of the large variety of complement components (Table 2). This is also reflected by their genomic location and gene structure, as a number of structurally and/or functionally closely related components are organized in major gene clusters in the human genome. These findings support assumptions, based on homology studies at the protein level, that the majority of complement components have evolved by duplication from only a small number of precursor genes.

Table 1 Summary of polymorphisms and deficiency of complement components in humans and animals

Complement component	Typing technique	Total no. of known alleles	Deficiency	Polymorphism in other species	Disease associations
C1q	Imm/Funct	—	Yes	—	Yes
C1r	IEF+WB	>10	Yes	—	Yes
C1s	IEF+WB	2	Yes	—	Yes

Typing techniques: EXP, expression polymorphism (number of membrane-associated molecules per cell); Funct, Functional assay; HAI, Hemagglutination inhibition with human alloantisera; HOV, Complement component-dependent hemolytic overlay; HVAGE, High-voltage agarose gel electrophoresis; IEF, Isoelectric focusing; IFX, Immunofixation; Imm, Immunologic detection with specific antisera; MAB, Monoclonal antibodies; RFLP/PCR, DNA restriction fragment length polymorphism detected by Southern blot or polymerase chain reaction analysis; SDS-PAGE, SDS polyacrylamide gel electrophoresis; WB, western blot.

Animal species: Ba, Baboon; Ch, Chimpanzee; D, dog; Gp, guinea pig; Hm, hamster; HI, Hanuman langur monkey; Mc, Macaque; Ms, mouse; Rb, rabbit; Rh, Rhesus monkey; XI, *Xenopus laevis*.

Regulators of complement activation (RCA) gene cluster on human chromosome 1

This cluster includes genes for complement receptors CR1 and CR2, the decay-accelerating factor (DAF), the membrane cofactor protein (MCP), factor H (HF), and the C4-binding protein (C4BP). All six proteins share common sequence motifs called short consensus repeats (SCR) of about 60 amino acids in

length. In addition, multiple RNA transcripts due to alternative splicing have been described for most members of this cluster. Since this tightly-linked gene family controls the activity of the complement system, it is hard to escape the conclusion that genetic linkage is the evolutionary concept for the maintenance of closely related functions.

Table 2 Chromosomal assignments of complement components and related proteins

<i>Component (or subunit)</i>	<i>Gene symbol</i>	<i>Chromosomal location</i>
C1q: α chain	C1QA	1p34.1–p36.3
C1q: β chain	C1QB	1p34.1–p36.3

Membrane attack complex (MAC) components C6, C7 and C9 on human chromosome 5

Another gene cluster of complement components was assigned recently to chromosome 5. It has been

known for some time that C6 and C7 of the terminal complex are genetically linked, evidence of which was mainly derived from a case of combined C6/C7 deficiency. Whereas the C6 and C7 genes are closely linked (only about 160 kb apart), the C9 gene is

located at a distance of >2.5 mb. These three genes share a number of common structural features with those of the C8 α and β chains (C8A and C8B) on chromosome 1: a central cysteine-poor region flanked by several thrombospondin, epidermal growth factor (EGF) precursor and low-density lipoprotein (LDL) receptor repeats. The genes of the MAC may have evolved by duplication and translocation from an ancestral precursor functionally related to perforin, a pore-forming protein of cytotoxic T cells.

C2, factor B and C4 as class III components of the major histocompatibility complex (MHC) on human chromosome 6

These central components of the classical and alternative pathway are encoded in a 120 kb stretch of DNA flanked by the genes of class I and II MHC antigens, HLA-A, -B, -C and -DR, -DQ and -DP, respectively. Although the C2 and BF genes differ significantly in size, they share extensive homology in the coding sequence (both are precursors of functional serine proteases) and have arisen by gene duplication. No homozygous factor B deficiency has yet been reported. Homozygous C4 deficiency is a rare condition and regularly associated with autoimmune or immune complex disease (e.g. systemic lupus erythematosus (SLE) or SLE-like disease). In contrast, about two-thirds of homozygous C2-deficient individuals appear to be healthy, although cases with SLE-like disease or bacterial infections have been described. Whereas there is only a limited polymorphism of C2 and BF, the fourth component of humans is encoded by two closely linked loci – C4A and C4B – exhibiting an extensive polymorphism with a total of more than 30 alleles. Two duplicated and functionally active C4 loci are found only in higher primates and humans. In all mammals (except for the rabbit), as well as in amphibians, the class III complement genes are located in the MHC.

Complexity of the fourth component of human complement with regard to molecular basis, functions and disease associations

For a number of reasons, human C4 is unique among all complement components with regard to its genetic basis, the subtle functional differences of isotypes and allotypes as well as its potential role in the pathogenesis of disease:

1. Human C4 has the most complex molecular basis: the C4A and C4B genes encode proteins with 99% sequence homology but clearly differ-

ent functions. The two isotypes differ only in a single serologic determinant defined by amino acid residues of the α -chain. A single amino acid substitution from Lys to Pro at position 1101 is responsible for an apparent molecular weight change of 2 kDa on SDS-PAGE; the change from Asp to His at position 1106 alters the hemolytic activity by three- to fourfold. Further, both loci contain so-called 'null' alleles C4Q0 (= quantitative zero), which express no detectable gene product, at remarkable high frequencies (10–20%). These 'silent' alleles are due to: deletions of an entire C4 gene including one of the adjacent genes of steroid 21-hydroxylase, CYP21 (such as C4AQ0 in the most common Caucasoid HLA haplotype A1-Cw7-B8-C2C-BFS-C4AQ0B1-DR3), gene conversion from one C4 isotype to the other (e.g. in the HLA haplotype B44-C2C-BFS-C4A3BQ0-DR4), or non-expression of structural genes due to individual point mutations (e.g. in the HLA haplotype B60-C2C-BFS-C4AQ0B2-DR6). In addition, a number of haplotypes with structurally duplicated C4 genes have been found.

2. Different functions have been ascribed to the thiolester bond of nascent C4b: C4A preferentially transacylates on to amino group nucleophiles, whereas C4B prefers hydroxyl groups for ester formation. Furthermore, C4A is 1.7-fold more efficient at inhibiting immune precipitation than C4B. Complete C4-deficient serum has almost no neutralizing activity in a mumps virus neutralization assay; purified C4A enhances the reaction about tenfold compared with C4B. Immunization experiments with complement-deficient guinea pigs have provided evidence that both C4 isotypes play distinct roles in the induction and amplification of the T cell-dependent immune response.
3. There is a steadily growing list of associations (of variable confidence) of C4 deficiency with a wide variety of diseases such as SLE, rheumatoid arthritis, systemic sclerosis, subacute sclerosing panencephalitis (SSPE), primary biliary cirrhosis, chronic polyarthritis, multiple sclerosis, visceral leishmaniasis, chronic glomerulonephritis, leprosy, Brazilian paracoccidioidomycosis, common variable immunodeficiency, immunoglobulin A deficiency, insulin-dependent diabetes mellitus, Chagas disease and the acquired immune deficiency syndrome (AIDS). A number of autoimmune diseases are associated with the HLA haplotype A1-Cw7-B8-C4AQ0B1-DR3.

Possible mechanisms of complement and disease associations

Since only some, but not all, complement-deficient individuals show disease manifestations, it appears legitimate to conclude that the deficiency is the common genetic basis, not the primary cause in the pathogenesis of a given disease. Also, there is no direct evidence for a role of single genetic variants of a given component in the pathogenesis of autoimmune or infectious diseases. However, there are several lines of evidence suggesting an important physiologic role of complement in immune defense:

1. It has been shown that the intact classical pathway is needed to prevent formation of insoluble immune complexes (ICs); the components of the classical pathway play an important role in this function. In cases of deficiency, ICs may not be cleared by the reticuloendothelial system and therefore recirculate until being deposited at capillary or basal membranes, leading eventually to tissue damage. This mechanism could be envisaged in some forms of vasculitis and glomerulonephritis, as well as autoimmune disease in the presence of nuclear antibodies.
2. In the case of viral antigens, small ICs may escape from CR1-mediated clearance by erythrocytes if the individual is C4-deficient. Circulating ICs may even, after years, be deposited in the brain, having passed the blood-cerebrospinal fluid barrier, contributing to cytotoxic effects in the central nervous system, as seen in diseases such as SSPE and AIDS.
3. Deficiency of MAC components may render these individuals more susceptible to recurrent infections with bacteria such as *Neisseria*. On the other hand, the lack of complement-dependent bacterial lysis protects the patient from massive levels of bacterial endotoxin, leading to a milder course of disease. Depending upon the structural components of the bacterial membranes, some strains appear to be more resistant to complement-mediated lysis than others.

Concluding remarks

A deep insight into the complex genetic structure of most complement components and their evolution has been gained in the last decade. A number of genetic abnormalities of complement components have been observed in association with disease. It is, however, still premature to bridge the variation or loss of *in vitro* functions to a given *in vivo* situation. It will be an important task to replace the statistical relationship of a disease association by the eluci-

dation of causal factors in the pathogenesis of complement-related diseases, as well as to establish evidence for a functional relevance of polymorphic complement allotypes in the natural selection process.

COMPLEMENT, MEMBRANE ATTACK PATHWAY

Agustin P Dalmasso, Department of Laboratory Medicine and Pathology,
VA Medical Center and University of Minnesota, Minneapolis, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The membrane attack pathway represents a common effector mechanism of the classical and alternative pathways of complement activation. Activation of the membrane attack pathway constitutes the last stage of complement activation and results in assembly of a multiprotein complex known as the membrane attack complex (MAC). The MAC is comprised of the complement components C5b, C6, C7, C8 and C9 (Table 1). Assembly of the MAC on the surface of a cell may have two major consequences. First, the MAC may activate a series of cellular processes that result in MAC elimination as well as cellular responses that are mostly pro-inflammatory. Second, if sufficient MAC attaches to a cell membrane, cell death may ensue. The name MAC derives from this latter property as the complex can damage a cell membrane independently of the binding of earlier complement components to that cell.

Assembly, structure and control of the MAC

The first step in assembly of the MAC is the generation of C5b from C5. This is accomplished through cleavage of C5 into C5a and C5b by the C5 convertases of the classical pathway (C4b2a3b) or the alternative pathway (C3bBbC3b) (Figure 1). C5 binds to C3b which serves both as an assembly site and a cofactor for the enzyme site in the C5 convertases that cleave the α chain of C5, generating C5a and C5b. Then C5b interacts with the terminal complement proteins in a nonenzymatic sequential association, resulting in assembly of the MAC (Table 1 and Figure 1). As each protein incorporates into the complex a conformational rearrangement produces a binding site for the next component. After generation C5b exposes a binding site for C6 with a half-life of 2.3 min at 37°C. Binding of C6 to the

Figure 1 Diagrammatic illustration of the complement membrane attack pathway and electron microscopy of MAC protein complexes. Reaction sequence from activation of C5 through assembly of the complete MAC is shown. Interaction of complexes with a cell membrane is illustrated, with C8 depicted in black. Stippled areas indicate membrane pores of progressively larger size that develop in parallel with progression of MAC assembly. Arrows indicate loss of permeability barrier. Also shown are electron micrographs of membranes bearing C5b-7 (panels a and b), C5b-8 (panel c) and the fully assembled MAC (panel d, lateral view, and panel e, top view). (Electron micrographs are reproduced from RR Dourmashkin (1978), The structural events associated with the attachment of complement components to cell membranes in reactive lysis, *Immunology* **38**: 205-212, with permission from the publisher.)

transient site is facilitated by the weak association of C5 and C6 in solution. The resultant C5b6 is stable and has a binding site for C7. C5b6 can remain loosely associated with C3b, which assists in directing C5b-7 to the adjacent membrane, or detach to the fluid phase. Once C7 incorporates into the

complex a metastable binding site with a high affinity for phospholipids is produced. This site is very short-lived, less than 10 ms, and allows the C5b-7 complex, after detachment from C3b, to anchor in the external surface of the lipid bilayer, primarily through C7. The electron microscopic appearance of

membrane-bound C5b-7 is that of a foliaceous particle (Figure 1). Assembly of the complex can also continue in the fluid phase; however, competition for the lipophilic binding site precludes attachment to a cell membrane. Vitronectin, clusterin, lipoproteins and C8 can all bind to fluid phase C5b-7 and prevent further association with membrane phospholipids.

Membrane-associated C5b-7 binds one molecule of C8, forming the C5b-8 complex, which then may bind multiple molecules of C9. The C5b-7 complex in the membrane bilayer binds a C8 molecule by interaction of the C8 β chain with C5b; possibly a second binding site on C7 promotes a conformational rearrangement in C8 resulting in the C8 α chain penetrating the lipid bilayer. Bound C5b-8 appears as a particle with a variable number of arms (Figure 1), with C5b and C8 β most distal from the membrane. The resultant C5b-8 complex has a greater affinity for phospholipids than C5b-7, penetrates more deeply into the membrane and disrupts membrane integrity to produce small transient ion-permeable channels. C9 binds to the C8 α chain in the C5b-8 complex and undergoes a conformational change that allows C9 to insert through the bilayer and expose additional binding sites for C9 polymerization. The C5b-9 complex has a greater affinity for phospholipids than C5b-8 and the membrane channel becomes more stable. The channels are formed by the disruption of the bilayer structure as membrane phospholipids attach to the complex. Additional molecules of C9 incorporate into the complex in a circular configuration and the size of the channel continues to increase (Figure 1). Incorporation of 12-18 molecules of C9 results in formation of the closed ring, tubular polyC9 structure, which may function as a protein-walled channel. The ultrastructure of this complex on top view corresponds to a ring with an internal diameter of 10 nm and an external diameter of 21 nm. On a lateral view there is a pedicle attached to polyC9 that represents the majority of the C5b-8 complex and extends 16 nm beyond the ring which has a height of 15 nm. Penetration of a membrane by the C5b-9 complex results in loss of membrane phospholipids and a reduction in membrane fluidity. Phospholipids and cholesterol in red cell membranes that have been exposed to the MAC are resistant to dissociation by caotropic agents.

MAC assembly is controlled by several regulatory mechanisms that protect tissues from damage by physiologic activation of autologous complement. Inhibition of early events of complement activation reduces formation of C5 convertases and thus prevents generation of C5b and MAC. Even after C5b has been produced there are mechanisms that control

MAC assembly. Intrinsic control is provided by the lability of the exposed binding sites in C5b and C5b-7. There are also membrane-bound and plasma inhibitors that prevent further assembly of complement proteins into the complex. The membrane-associated inhibitors are homologous restriction factor (HRF) and CD59 (also called protectin, MAC inhibitory factor or HRF20) and they are more effective to protect a cell from lysis by complement of the same species than by complement from other species (homologous restriction). CD59 and HRF inhibit formation of the MAC through interaction with membrane-bound C5b-8 to impair the binding of C9 and with C5b-9 to block additional binding and polymerization of C9. These inhibitors are expressed on most cells that are in contact with blood or other biological fluids containing complement. These proteins as well as the inhibitor of the C3 and C5 convertases decay-accelerating factor (DAF) are anchored to the membrane through a glycosyl phosphatidylinositol moiety, although in certain cells they may also exist as transmembrane proteins. There are also plasma proteins that control MAC formation. Vitronectin (S protein) and clusterin (SP-40,40) are multifunctional proteins that interact with late-acting complement components as complexes assemble in plasma, and inhibit binding of the protein complex to cell membranes. In addition, apolipoproteins A-I and A-II may inhibit MAC formation by interfering with polymerization of C9.

Physiologic and pathologic significance of the MAC

The MAC is endowed with the potential to inflict damage on cell membranes that may result in cell death and to induce cellular responses that are generally proinflammatory. These activities may participate significantly in varied physiologic and pathologic processes. Induction of cell damage is a consequence of the ability of the MAC to generate ion-permeable channels in the cell membrane. Membrane-bound C5b-8 can lyse red cells at a low rate but this process is enhanced by C9. Because of the strong affinity of C5b-8 for phospholipids, the membrane bilayer is disrupted, causing increased permeability, which is further enhanced by larger channels formed by addition of C9. Addition of one C9 molecule per C5b-8 is sufficient for rapid lysis of red cells. The permeability changes may cause osmotic swelling and lysis of red cells. Red cells are able to offer some resistance to osmotic swelling by means of a Ca^{2+} -activated K^{+} channel and may repair lesions through a Ca^{2+} -dependent vesiculation process. Killing of nucleated cells by the MAC is

independent of permeability changes and is associated with an increase in cellular Ca^{2+} and intracellular lipid metabolism, mitochondrial swelling, and hydrolysis of membrane lipids. Nucleated cells are capable of defending themselves from the cytotoxic effect of the MAC and, consequently, lysis is achieved only when large numbers of MAC with multiple C9 are deposited on the plasma membrane. Sublytic amounts of MAC induce activation of the target cell, which, among other effects, results in energy-dependent elimination of membrane-bound MAC by endocytosis or exocytosis. This process requires extracellular Ca^{2+} , with participation of protein kinase C (PKC) and cAMP. Cells with increased levels of cAMP are resistant to MAC-mediated killing. Conversely, inhibition of protein synthesis or lipid metabolism increases susceptibility to MAC-mediated killing.

The MAC plays a role in host defense processes through its ability to kill certain microorganisms and to promote inflammation. The function of the MAC in protection against infections is best demonstrated in individuals with homozygous deficiency of a MAC protein. These individuals have increased susceptibility to develop disseminated disease when infected with the gram-negative organism *Neisseria gonorrhoeae* or *N. meningitidis*. Thus killing by the MAC must be essential to maintain localization and prevent dissemination of neisserial infections. Other gram-negative bacteria, but not gram-positive bacteria, may be killed by the MAC; however, susceptibility is variable. In general smooth strains, but not rough strains, are resistant to killing because they are protected from the MAC by long-chain lipopolysaccharides. For bactericidal activity the deposits of MAC on the bacterial surface must contain at least three molecules of C9 per C5b-8. Enveloped viruses and parasites may also be susceptible to the cytotoxic effect of the MAC. The poor susceptibility to MAC-mediated killing of many microorganisms is due to their defense mechanisms against complement, including certain surface proteins that are homologous to human complement inhibitors.

In vitro studies have shown that formation of sublytic amounts of MAC on the surface of nucleated cells may trigger certain transduction pathways that may result in generation of mediators of inflammation. Even the C5b-7 complex, which binds to membranes but does not form a channel, is able to induce in certain cells an increment in cAMP, diacylglycerol (DAG) and ceramide. C5b-8 and C5b-9 in sublytic amounts can activate several transduction pathways mainly through the participation of Ca^{2+} which first enters the cell through the MAC pore and then triggers the release of Ca^{2+} from intracellular

organelles. Transduction pathways that are Ca^{2+} -independent may also be activated. The MAC can induce activation of PKC and stimulate phosphoinositide metabolism, with increased production of IP_1 , IP_2 and IP_3 , and increase the intracellular concentration of *sn*-1,2-diacylglycerol. The MAC can also interact with pertussis toxin-sensitive guanine nucleotide-binding proteins (G proteins). C5b-9 causes arachidonic acid release, which in part requires external Ca^{2+} , resulting in production of DAG, which may activate PKC and thus stimulate phospholipase A_2 . The MAC may induce cell cycle in oligodendrocytes, which involves *c-jun* activation, and can also cause hydrolysis of myelin basic protein.

Through these and possibly other cell activation mechanisms, the MAC may induce the synthesis of soluble and membrane-associated inflammatory mediators. Thus, it may stimulate the conversion of arachidonic acid into various metabolic products, including prostaglandins, thromboxanes and leukotrienes, and facilitate the production of interleukin 1 (IL-1), tumor necrosis factor α (TNF α) and oxygen-derived free radicals. In endothelial cells, the MAC stimulates the secretion of IL-8 and monocyte chemoattractant protein 1, and inhibits endothelial cell-dependent relaxation, and C5b-7 causes endothelial cell retraction. The MAC may also modify the expression of adhesion molecules in endothelial cells, resulting in upregulation of P-selectin and secretion of von Willebrand factor. In endothelial cells that have been pretreated with TNF α , the MAC enhances the expression of E-selectin and ICAM-1. The MAC is able to directly stimulate mitogenesis in target cells and may also induce the release of mitogenic substances from endothelial cells. In addition to causing cell activation and production of several inflammatory substances, molecules such as cAMP may exit the cell through the C5b-9 channel and modulate the function of neighboring cells.

The MAC plays an important pathophysiologic role in several autoimmune and inflammatory diseases. In some cases this may be due to its cytotoxic effect, as in several immune hematologic diseases. In many instances, however, the pathophysiologic participation of the MAC is more likely related to its ability to elicit cell activation when present in sublytic amounts. The MAC has been implicated in renal diseases such as acute poststreptococcal glomerulonephritis, membranous and membranoproliferative type III nephropathy and lupus nephritis, in neurological diseases such as multiple sclerosis, Guillain-Barré syndrome and myasthenia gravis, in rheumatoid arthritis and immune-complex vasculitis, and in the extension of myocardial infarction lesions and

ischemia-reperfusion injury. The MAC also plays a major role in hyperacute rejection of allografts and xenografts. In xenografts this rejection is in part due to the fact that the complement inhibitors are inhibitory to homologous complement but have little inhibitory capacity upon complement from a different species. For this reason transgenic donor pigs that express human complement inhibitors such as CD59 and DAF have been prepared and are being tested in nonhuman primates. The complement-mediated xenogeneic tissue injury is less severe in pig organs that express the human inhibitors than in organs from control pigs.

The biological importance of the inhibitors CD59 and DAF in protection of host cells against physiologic activation of autologous complement is highlighted by the disease paroxysmal nocturnal hemoglobinuria. This condition is caused by an acquired mutation in a gene for one of the enzymes that participates in the synthesis of the glycan phosphatidylinositol moiety shared by the complement inhibitors and certain other membrane proteins. As a consequence the peripheral blood cells derived from the mutant stem cell have low or absent expression of CD59 and DAF and are highly susceptible to complement mediated lysis. A role for the membrane-associated complement inhibitors, including CD59, in resistance of cancer cells to complement-mediated control has been proposed. However, human malignancies that express little or no complement inhibitors do not appear to have a better course than malignancies that express large amounts of inhibitors.

COMPLEMENT RECEPTORS

Gordon D Ross, Division of Experimental Immunology and Immunopathology, Department of Pathology, University of Louisville, Louisville, Kentucky, USA

Complement (C) receptors were first reported by Levaditi and Inmann, in 1905, who found that phagocytic cells exhibited enhanced ability to ingest bacteria after treatment with fresh antisera that served as a source of complement as well as antibacterial antibody. This process, termed opsonization, was subsequently shown to involve the coating of bacteria with C3 molecules that facilitated attachment of the bacteria to membrane C3 receptors expressed on the phagocytes (i.e. neutrophils or monocyte/macrophages). Later, in 1930, Duke and Wallace observed that complement-opsonized trypanosomes bound to primate red blood cells, producing the phenomenon that was named immune adherence by Robert Nelson in 1953. Nelson was the first to demonstrate that immune adherence with red blood cells or neutrophils required only the activation of C3, and not the terminal lytic complement components. The immune adherence receptor of erythrocytes and neutrophils was subsequently named complement receptor type 1 (CR1) when the existence of other types of C3 receptors was appreciated (Table 1). Four additional types of C3 receptors have been named according to their order of discovery. CR2 (1973), CR3 (1979), CR4 (1984) and CR5 (1984). Four receptors for other complement components and for C3a have been named according to their ligand specificity: C1q-R (C1q receptor, 1975), C5a-R (C5a receptor, 1978), C3a-R (C3a receptor, 1979), fH-R (factor H receptor, 1980). In addition, several of the complement receptors have been recognized as leukocyte CD antigens by the International Leukocyte Antigen Workshop: CR1 is CD35, CR2 is CD21, CR3 is CD11b, CR4 is CD11c, and C5a-R is CD88. Complement receptors have a wide range of functions that include, in addition to phagocytosis, enhancement of B cell antigen recognition, removal of immune complexes from the blood, release of histamine from mast cells, and chemotaxis of phagocytic cells to sites of inflammation.

Structure, specificity and cellular distribution of complement receptors

Complement receptor type 1 (CR1)

CR1 (CD35) binds to C3b, and with lower affinity to C4b and iC3b. Proteolysis of iC3b into C3dg

destroys CR1 activity. Several cell types express CR1, including erythrocytes, phagocytic cells, lymphocytes (B cells and some T cells), kidney podocytes and peripheral nerves. CR1 along with CR3, CR4 and immunoglobulin G (IgG) Fc receptors are the major opsonin receptors on phagocytic cells. The CR1 of erythrocytes has two important functions in the clearance of circulating immune complexes. First, immune complexes and particles that activate complement are bound rapidly to erythrocytes via CR1. Erythrocytes then serve as a vehicle that transports the complexes to the liver and splenic macrophages. Second, erythrocyte CR1 function as the obligate cofactor for factor I cleavage of complex-bound iC3b into bound C3dg and fluid-phase C3c. B cell CR1 forms a membrane complex with CR2 that functions to promote the uptake of protein antigens that are coated with C3b or iC3b via natural antibodies and the classical pathway of complement activation. Antigen complexes that are bound to the CR1 portion of this B cell membrane complex via C3b are transferred to CR2 following proteolysis of the C3b into iC3b and C3dg. T cell CR1 may have a similar antigen-trapping function, but only small subsets of CD4⁺ and CD8⁺ T cells express CR1, and the amount of CR1 expressed per cell is ≤10% of that expressed by B cells.

CR1 is a member of a family of proteins known as the 'regulators of C activation' (RCA) that are encoded by chromosome 1 in humans. Other RCA members include CR2, factor H, decay accelerating factor (DAF, CD55), membrane cofactor protein (MCP, CD46), and C4-binding protein or C4-BP. CR1 exists in four allotypic forms that vary in size from 160 kDa to 250 kDa. Analysis of CR1 cDNA has demonstrated that CR1 consists of 3–5 linked protein segments that exhibit a high degree of internal sequence homology and are termed 'long homologous repeats' (LHRs). Allotypic variation in the number of LHRs per CR1 explains the large size variation in the CR1 from different individuals. Each LHR consists of seven short (60–70 amino acid) repeating sequence motifs ('short consensus repeats', SCRs). These SCR motifs are the common feature of the RCA proteins that apparently explain their C3b- and C4b-binding activity. Variations in SCR sequence determine binding activity, and distinct SCR sequences in CR1 confer either C3b- or C4b-binding activity.

Table 1 Structure, specificity and cellular distribution of complement receptors

Receptor type	Specificity	Structure	Cell type distribution
CR1 (CD35)	C3b > C4b > iC3b	Four allotypes that vary in size from 160 kDa to 250 kDa due to different numbers of repeating sequence motif units	Monocytes, neutrophils: high expression Tissue macrophages: low expression B cells, eosinophils: high expression Kidney podocytes: high expression T cells (~20%): low expression Peripheral nerves: low expression
CR2 (CD21)	iC3b = C3dg > C3d > C3b, Epstein-Barr virus, CD23	Made up of repeating sequence motif units similar to CR1; 140 kDa	B lymphocytes: high expression Lymph node follicular dendritic cells: very high expression Thymocytes, pharyngeal epithelial cells: low expression
CR3 (CD11b; Mac-1; $\alpha_M\beta_2$ -integrin)	iC3b, C3dg, C3d, β -glucan, ICAM-1, fibrinogen, factor X, collagen, heparan sulfate, CD14, CD16, CD87	Two noncovalently linked glycoprotein chains: 165 kDa α_M chain (CD11b), 95 kDa β_2 chain (CD18)	Neutrophils, monocytes: high expression Tissue macrophages: low expression Activated cytotoxic T cells, NK cells, eosinophils: high expression
CR4 (CD11c; p150,95; $\alpha_X\beta_2$ -integrin)	iC3b, C3dg, fibrinogen	Two noncovalently linked glycoprotein chains: 150 kDa α_X chain (CD11c), 95 kDa β_2 chain (CD18)	Neutrophils, monocytes: low expression Tissue macrophages: high expression Activated B cells: high expression Activated cytotoxic T cells, NK cells, eosinophils: low expression
CR5	C3d portion of fluid-phase iC3b, C3dg, C3d	Unknown; 95 kDa candidate molecule expressed by platelets	Neutrophils: low expression Platelets: low expression
gC1q-R	C1q globular 'head', as well as vitronectin and high molecular weight kininogen	33 kDa glycoprotein	All leukocyte types: variable expression Platelets: high expression Endothelial cells: high expression
cC1q-R	C1q collagen 'tail'	60 kDa glycoprotein; homologous to calreticulin	All leukocyte types: variable expression
C1q-R _p	C1q collagen-like fragment, mannose-binding protein, lung surfactant protein A	126 kDa glycoprotein	Neutrophils: high expression Monocytes: high expression
C3a-R	C3a, C4a	Guinea pig platelet: 95–105 kDa Human mast cell: 57 kDa and 97 kDa Human leukocyte: 482 amino acids, ~54 kDa, seven membrane-spanning domains	Mast cells: high expression Eosinophils, basophils: high expression Neutrophils, monocytes: low expression Guinea pig platelets: high expression
C5a-R (CD88)	C5a, C5a _{des Arg}	47 kDa glycoprotein binding unit with seven membrane-spanning domains expressed as an oligomer of 150–200 kDa	Mast cells, neutrophils: high expression Monocytes and tissue macrophages: high expression Eosinophils: high expression Hepatocytes, astrocytes, endothelial cells: high expression

In the mouse there is a closer relationship between CR1 and CR2, and the two membrane glycoproteins are derived from a single gene by alternative splicing of mRNA. As a result, the larger 190 kDa murine CR1 molecule contains the entire 140 kDa CR2

sequence as part of its structure. Monoclonal antibodies to CR2 are therefore equally reactive with CR1 and unable to distinguish the two types of C3 receptors. Murine CR1 appears to be restricted to B cells, and is not expressed on neutrophils or macro-

phages for phagocytosis, nor is it expressed on erythrocytes or platelets where it could function in immune complex clearance. Murine neutrophils and platelets express instead distinct C3b/C4b-binding molecules that appear structurally unrelated to CR1 or CR2.

Complement receptor type 2 (CR2)

CR2 (CD21) is expressed by B lymphocytes, lymph node follicular dendritic cells, pharyngeal epithelial cells and thymocytes. Only minor subsets of T lymphocytes express CR2, and the amount per cell is only 10% of the amount expressed by B cells. CR2 is not only a receptor for C3 fragments but also functions as the cellular attachment site for Epstein-Barr virus (EBV) and the counterligand for CD23. CR2 is specific for the C3d portion of iC3b, C3dg or C3d, and has only a low affinity for C3b. B cell CR2 has been shown to play a major role in primary and secondary antibody responses to protein antigens. In a primary response, natural antibodies form immune complexes with protein antigens, resulting in activation of the classical complement pathway and covalent fixation on to the antigen of C3b that is rapidly degraded by factor I into iC3b and C3dg. This bound C3 promotes efficient antigen uptake by B cells via CR2, and the resulting CR2 stimulation of the B cell lowers the antigen concentration threshold required for antigen recognition by specific surface Ig on the B cell. CR2 signaling results from a B cell membrane complex of glycoproteins that includes CR2, CD19 and TAPA-1 in which transmembrane signaling occurs via the CD19 portion of the complex. This pathway for use of complement and CR2 for antigen recognition was initially demonstrated with blocking antibodies to C3 or to CR2, and then later with gene knockout mice deficient in either C3, C4 or B cell CR2. Although an immune response could be generated in these mice with greatly increased antigen doses as compared with those required in normal mice, antibody levels were abnormally low, isotype switching did not occur, and there was no immunologic memory. This pathway for humoral immunity to protein antigens represents an important link between the innate and specific immune systems.

B cell isotype switching to IgE production also involves CR2 and its ability to form membrane complexes with the IgE receptor CD23. However, in a subversion of its normal function, CR2 is utilized by EBV to gain entry into B cells, permitting virus infection (infectious mononucleosis) or a malignant transformation of B cells or epithelial cells (Burkitt's lymphoma or nasopharyngeal carcinoma, respectively).

CR2 consists of a single polypeptide chain of

140 kDa with the same type of SCR structure as CR1. The CR2 gene is closely linked to the CR1 gene, and, in the mouse, a single gene transcribes both receptor proteins via alternative RNA splicing.

Complement receptor type 3 (CR3)

CR3 (also known as CD11b/CD18, Mac-1, or $\alpha_M\beta_2$ -integrin) is a multifunctional membrane protein that serves as both a membrane receptor to trigger phagocyte and natural killer (NK) cell cytotoxic events and as an adhesion molecule used by leukocytes for diapedesis across the endothelium (via attachment to ICAM-1) or the extracellular matrix (via attachment to heparan sulfate or fibrin). The I domain of CD11b binds with high avidity to opsonizing iC3b attached to microorganisms, and with lower avidity to opsonizing C3dg or C3d. However, its receptor function is complex, because CR3 not only recognizes exogenous target cell-associated ligands directly but also extends its effective ligand specificity by coupling itself to certain other endogenous leukocyte membrane receptors that utilize CR3 for their transmembrane signaling function. Critical to both forms of receptor activity is a lectin site located C-terminal to the I domain of CD11b and involved in recognition of either microbial cell wall polysaccharides or the leukocyte membrane glycoproteins that couple to CR3 for transmembrane signaling. Bacteria or yeast that bear opsonizing iC3b trigger CR3 activation because of simultaneous recognition of microbial cell wall polysaccharides via the CR3 lectin site and bound iC3b via the I domain. Potential target particles that bear fixed iC3b but lack specific polysaccharides recognized by this lectin site of CR3 do not stimulate cellular activation, despite avid adhesion of the particles to CR3 via the fixed iC3b. Ligation of polysaccharides to the lectin site of CD11b induces a tyrosine kinase- and magnesium divalent cation-dependent conformational change in CD11b that is associated with generation of a primed state of CR3 capable of stimulating cellular cytotoxic activation events (e.g. phagocytosis, degranulation) when CR3 subsequently attaches to target cell-bound iC3b via its I domain-localized binding site. Three neutrophil membrane receptors that are attached to membranes via surface phosphatidylinositol glycolipid (PIG) bridges acquire transmembrane signaling function by forming lectin site-dependent complexes with the transmembrane CR3 molecule: 1) the IgG Fc receptor Fc γ RIIIA (CD16), 2) the urokinase plasminogen activator receptor (uPAR or CD87), and 3) the lipopolysaccharide (LPS) receptor (CD14).

Unlike C-type (calcium-dependent) lectins, the polysaccharide-binding site of CR3 does not require divalent cations and has a relatively broad reactivity

with certain polysaccharides containing mannose or N-acetyl-glucosamine, as well as glucose (β 1,3-glucans).

Unstimulated phagocytes express small amounts of membrane CR3 and retain large stores of CR3 in cytoplasmic granules. Following stimulation with C5a or a variety of cytokines, much of the initial membrane surface CR3 becomes linked to the actin cytoskeleton in a way that renders it capable of mediating phagocytosis or extracellular adhesion to ICAM-1. Simultaneously, specific granules come to the cell surface, where their membranes fuse with the outer cell membrane, greatly increasing the expression of membrane surface CR3. However, this granule-derived CR3 is not linked to the cytoskeleton and is thus incapable of mediating firm cellular adhesions or phagocytosis. This more abundant but loosely associated CR3 is very mobile within the membrane and functions to promote phagocyte attachment to iC3b-coated target cells, allowing their subsequent phagocytic recognition by the less mobile but cytoskeleton-bound CR3 (or CR4).

CR3 consists of two noncovalently associated glycoprotein chains known as α_M or CD11b (165 kDa) and β_2 or CD18 (95 kDa). CR3 is one of four members of the leukocyte β_2 -integrins that share the common β_2 -integrin structure linked to a distinct α -chain type. The other three leukocyte β_2 -integrins are LFA-1 (CD11a/CD18), CR4 (CD11c/CD18 or p150,95) and CD11d/CD18.

Complement receptor type 4 (CR4)

CR4 (CD11c/CD18 or p150,95), the third member of the leukocyte β_2 -integrins, is closely related to CR3. The CR4 α chain (CD11c, 150 kDa) is ~87% homologous in sequence to CD11b, and recognizes similar ligands including iC3b, fibrinogen and, according to some reports, even ICAM-1. CR4 is expressed preferentially on tissue macrophages that bear only small amounts of CR1 and CR3. Phagocyte CR3 and CR4 differ in cytoplasmic domain structure and attachment to the actin cytoskeleton, and this is thought to provide a mechanism for differential regulation of cellular adhesion or phagocytosis. The relative importance of CR4 as a receptor for iC3b is unclear, as most of the iC3b receptor function of leukocytes, including tissue macrophages, is blocked by use of antibodies to CR3 alone.

Complement receptor type 5 (CR5)

CR5 appears to be specific for the C3d portion of iC3b, C3dg and C3d, but reacts only with these fragments in the fluid phase and not when they are fixed via their normal covalent site. CR5 activity has been defined with fluid-phase dimers of C3dg labeled with

^{125}I . Neutrophil uptake of ^{125}I -C3dg dimers was blocked by competing unlabeled iC3b, C3dg and C3d, but not by C3b. At one time it was believed that the C3dg dimer receptor might be the same as the receptor for erythrocyte C3dg rosette formation, and so both receptor activities were designated CR4. Later, however, the receptor activity responsible for rosette formation was shown to have several properties that distinguished it from the C3dg dimer receptor, and so the C3dg dimer receptor was named CR5. The binding of CR4 to fixed iC3b was prevented by ethylene diamine tetraacetic acid (EDTA), whereas EDTA had no effect on the uptake of ^{125}I -C3dg dimers. Although CR5 activity has been identified on neutrophils and platelets, it is unknown whether the same molecule is responsible for this activity on both cell types. A platelet membrane glycoprotein of 95 kDa identified by affinity labeling techniques has been shown to function as a C3dg receptor. In the absence of sequence data established from a molecular clone, the existence of CR5 as a distinct entity is less certain than the other C3 receptors.

C1q receptors (C1q-R)

Three distinct types of C1q-R have been described: one that binds to the globular 'head' portion and two that react with the collagen 'tail'. All three of the receptors have been shown to react with other molecules in addition to C1q, such as vitronectin, kininogen and mannose-binding protein. A 33 kDa glycoprotein with affinity for the C1q globular head, 'gC1q-R', and a 60 kDa glycoprotein that reacts with the collagen tail, 'cC1q-R', were first identified on Raji B lymphoblastoid cells. Antibodies to these two molecules have now shown a wider cell type distribution, and gC1q-R is particularly expressed on platelets and endothelial cells, as well as eosinophils. A second type of receptor for the collagen portion of C1q is a 126 kDa monocyte and neutrophil membrane glycoprotein that has been termed C1q-R_p because of its ability to enhance phagocytosis mediated via CR1. The cDNAs for all three of these molecules have been cloned, and gC1q-R has been expressed as a recombinant molecule that retains C1q-binding activity. Although the two have novel sequences, the 60 kDa cC1q-R has considerable homology with calreticulin and may represent a membrane surface variant of this cytoplasmic protein. The 33 kDa gC1q-R is the product of a single gene localized to chromosome 17 and has a specificity similar to the Fc region of Ig. By contrast, cC1q-R and C1q-R_p do not compete with Ig Fc, and thus can promote cellular uptake of immune complexes bearing C1q linked to Ig. These latter types

of C1q-R bind immune complex-associated C1q preferentially, because single C1q molecules have a low affinity for cC1q-R or C1q-R_p, and the C1q binding site in native C1 is masked by C1r and C1s. The collagen binding site in C1q is exposed by C1 inhibitor that complexes with activated C1r and C1s, separating them away from C1q.

Factor H receptor (fH-R)

A fH-R activity has been detected on B lymphocytes, monocytes and neutrophils, but no structural comparison of the fH-R on these cell types has been carried out and the molecular entity representing fH-R has not been identified. Since plasma did not block cellular uptake of radiolabeled factor H, it was proposed that fH-R were unreactive with 'native' plasma factor H, and that either purification procedures or immune complex attachment might alter factor H in a way that exposed a binding site for fH-R. Subsequently, purified factor H preparations were shown to contain two species of factor H, designated ϕ_1 and ϕ_2 , that could be separated by phenyl-Sepharose hydrophobic affinity chromatography. Only the ϕ_2 form of factor H bound specifically to lymphoid cells, but it is unknown whether this ϕ_2 form of factor H exists in plasma or if it is generated by H interaction with immune complexes. The first attempt at isolation of the fH-R from lymphoblastoid cells used either antifactor H idiotype antibody or factor H-Sepharose and identified a protein complex of ≥ 150 M_r with 100 kDa and 50 kDa components. A second study using factor H agarose affinity chromatography detected a single protein species of 170 kDa on the surface of B lymphoblastoid cells and tonsil B cells. This 170 kDa protein bound specifically to factor H agarose, and in soluble form, prevented rosettes with factor H-coated erythrocytes. B cells have been shown to release endogenous stores of factor I in response to fluid-phase or immune complex-associated factor H, and purified H has been reported to serve as a growth factor for the maintenance of B cell lines.

C5a receptor (C5a-R)

The inflammatory functions of C5a are mediated via specific C5a-R (CD88) expressed on a variety of cell types including mast cells, phagocytes, bronchial and alveolar epithelial cells, hepatocytes, astrocytes and vascular endothelial cells. The action of C5a is regulated both by serum carboxypeptidase N (SCPN), which removes the C-terminal arginine (forming C5a_{des Arg}), and by neutrophil catabolism of C5a following specific uptake by C5a-R. Although C5a_{des Arg} has reduced binding affinity as compared with C5a, it is a major ligand for C5a-R *in vivo* because of the

serum protein ('cochemotaxin') that combines with the C5a_{des Arg} and enhances its action with C5a-R. Cochemotaxin is identical to GC globulin or vitamin D-binding protein. The ~47 kDa C5a-R glycoprotein is a member of the family of related G protein-linked chemokine receptors that have seven membrane-spanning domains. A two-site model has been suggested in which part of the N-terminal extracellular domain of the receptor recognizes the N-terminal and disulfide-linked core of C5a. This is then thought to be followed by interaction of the C-terminus of C5a with a second region of the receptor that is linked to G protein and responsible for the activating signal. Both the contractile responses of smooth muscle cells and the increased vascular permeability produced by C5a are thought to result from histamine release by mast cells or basophils that express the same C5a-R structure. C5a-R mediate a wide range of leukocyte responses, including chemotaxis, homotypic aggregation (clumping), activation of CR3 to expose its high-affinity binding site for ICAM-1 (thus promoting leukocyte adhesion to endothelium), and upregulation of the number of CR1, CR3 and CR4 exposed on external membrane surfaces. Larger doses of C5a cause degranulation and a respiratory burst. Because of the importance of C5a in mediating inflammatory responses, C5a-R antagonist drugs have been widely sought as therapeutic agents for autoimmune and inflammatory disease syndromes.

Receptor for C3a and C4a (C3a-R)

A single type of receptor is believed to be responsible for responses to C3a or C4a. This receptor activity was first characterized on mast cells, and later a similar C3a-R was demonstrated on basophils, eosinophils, neutrophils and guinea pig platelets. The first successful molecular cloning of the C3a-R was reported with cDNA libraries generated from differentiated HL-60 cells or U-937 cells. As with C5a, smooth muscle spasmogenic responses occur with nanomolar concentrations of C3a or C4a that stimulate mast cell secretion of histamine. Although disputed for many years, the chemotactic activity of C3a has now been shown with eosinophils and is likely to occur also with neutrophils or monocytes that express C3a-R. As with C5a, SCPN removes a C-terminal arginine from both C3a and C4a, greatly reducing, if not totally eliminating, the ability of these anaphylatoxins to stimulate cellular responses. Not only are all spasmogenic and leukocyte-associated activities of C3a and C4a absent in C3a_{des Arg} and C4a_{des Arg}, but also no cochemotaxin-like serum factor has been identified that restores C3a/C4a_{des Arg} activity in the same way as has been shown for C5a_{des Arg}. Attempts to identify a C3a-R with

¹²⁵I-C3a coupled to heterobifunctional cross-linking reagents identified a putative C3a-R only on guinea pig platelets and failed to identify a C3a-R on human platelets and neutrophils; however, similar methods were successful with a human mast cell line, HMC-1. These studies identified two putative guinea pig platelet C3a-R candidate molecules of 95 kDa and 105 kDa, and two human mast cell C3a-R species of 57 kDa and 97 kDa. Sequence homology with both the C5a-R (37% at the nucleotide level) and the fMLP-receptor allowed molecular cloning of the C3a-R. Cells expressing recombinant C3a-R exhibited the same reactivity with C3a as the native receptor, including the failure to bind C5a. Northern blotting with the 4.3 kb cDNA for C3a-R demonstrated transcripts of both 2.3 kb and 3.9 kb, perhaps explaining the two different sized receptors noted in cross-linking experiments. Based on the 2.3 kb transcript, a polypeptide of 482 residues was predicted with the typical seven membrane-spanning domains of the G protein-linked receptor family.

CONGENIC MICE

M Viviana Bozón and Edmond J Yunis, Division of Immunogenetics, Harvard Medical School, Boston, Massachusetts, USA

Inbreeding is the mating of individuals more closely related than mates chosen at random from a population. An inbred strain is a population that is almost genetically identical. Two animals (lines) that are genetically identical save for a difference at one locus

are called coisogenic (L. *co*, together; Gr. *iso*, identical).

When George D. Snell, working at the Jackson Laboratory, realized that rejection of a graft between two mice was affected by multiple genes, he

developed the concept of 'congenic mice', by transferring resistance genes from one mouse to another from a different genetic background. He produced lines by genetic backcrossing, and calculated that 12 generations were needed to obtain a line that differed from the original at one chromosomal region carrying an identified marker. While working on this breeding, Snell noticed that not only was there a locus intimately related to the rejection of tumor grafts, but another gene seemed to be retained from the donor strain, the *Fu* locus, a marker for a deformity of the tail. He named it the histocompatibility locus. During the development of the first congenic lines, Snell observed that some of the mice retained not only the tumor resistance but also marker genes of the donor strain. For example, the congenic line ACA, was produced from the inbred strain A and an outbred stock CA carrying the mutation fused tail (*Fu*). This not only carried the resistance to A strain tumors but also had the shortened tails caused by the *Fu* gene. This was the first demonstration of genetic linkage in mammals and the first genetic marker for the major histocompatibility complex later to be found by serology as H2.

At the same time, Peter Gorer in England discovered a hemagglutinating antibody associated with the rejection of transplantation of tumors. It appeared that a cytotoxic antibody responsible for this rejection was associated with blood group antigens. This was not considered a general rule for rejection, but the gene encoding this antigen was indeed located at the named 'H' locus. Gorer named the antigen 'antigen II'. In 1948, Gorer and Snell, working together, discovered that the H locus was linked to the tail marker (*Fu*) and was associated with rejection. Using congenic strains they found that skin grafts were rejected from the mice at different periods after the transplant. Experiments with different congenic strains produced support to the concept that some genes were associated with different degrees of influence in the rejection of allografts.

The H2 genes were identified as major genes and later were located in a single region at chromosome 17 named the major histocompatibility complex (MHC).

Congenic mice are useful tools for the analysis of the genetics of tissue and bone marrow transplantation, the genetics of the immune response including cellular interactions and the role of genes of the MHC in autoimmunity and longevity.

Production of congenic strains

Coisogenic strains are produced when an inbred mouse becomes genetically identical to another,

except with a difference at a single locus produced by mutation. This can be achieved by crossing mice in order to bear or introduce a small dominant region of one donor into a common genetic background. Therefore, congenic mice are two strains that are identical except for a short chromosomal segment. Coisogenic strains differ in one locus and congenic differ in a small variable region of a chromosome including several loci.

Backcrossing

The backcrossing procedure is applicable to the introduction of an autosomal dominant or codominant allele. The original pair, one inbred strain which donates the genetic background (first parent or inbred partner) and one donor strain which donates the chromosomal segment (second parent), are crossed. The F1 progeny are backcrossed to the inbred partner. For the next generation, a donor that poses the desired allele is selected. After 12 generations heterozygote siblings are mated, originating the desired genotype. At this point of the backcrossing, the offspring will be the progenitors of the desired congenic strain, which will be perpetuated by standard sibling mating (intercross) or by further backcrossing to the inbred parent.

The production of congenic strains of mice is based on the introduction of a short chromosomal segment into a second strain. The resulting strain is congenic. Molecular techniques are required to identify the marker gene of the genetic region that will be introduced into a common genetic background. Most of the existing congenic strains were named congenic resistant to indicate the introduction of genes that induced resistance to an incompatible tumor originating from a parent of the donor strain involved in the backcrossing. They differed from their inbred part at the histocompatibility locus. However, they can be produced for any genetic marker. The production of the strain B10.D2 is given as an example (Figure 1). In this example the genetic background is given by the B10 (C57BL/10SN) strain which is H2-b and the donor of H2-d of the strain DBQ/2J. The diagram shows that by a number of backcrosses, usually 10–15, it produces strains that differ from their inbred partner by a chromosomal segment 12–20 centimorgans (cM) long. In the case of the H2 (2 cM long) it would require at least 30 backcrosses to produce strains differing at less than 10 cM.

Essentially the backcrosses are tested for H2 markers (usually antibodies specific for MHC gene products). In the example of the figure, the homozygotic H2-b are discarded. The backcrosses are always between a b/d and the B10 inbred. It is important

Figure 1 Breeding system for producing congenic mice.

that the coisogenic strains differ only by a point mutation. When they are produced the level of probability is defined by the equation:

$$P_n = 1 - (1 - c)^{n-1}$$

where p = probability, n = number of generations and c = recombination frequency.

The higher the number of backcrosses the smaller the length of the differential chromosomal segment.

Genetics of the donor strains in congenic mice

The majority of the congenic mice were produced in the C57BL6 or C57BL10 mice (Table 1 gives examples of congenic and A mice background).

Symbols

The H2 complex occupies a segment of the chromosome 17 at a distance of some 15 cM from the centromere. The segment is between 0.1 and 1.5 cM long and contains a minimum of 10–15 loci. (The length of the segment and the number of loci in it depend on which loci one counts as belonging to the H2 complex.) To understand the designation of the congenic lines, Table 1 illustrates the strains (background partners) from which they originated

with the locations. These are some of the congenic strains that are available today at the Jackson Laboratory in Bar Harbor, Maine.

Congenic strains can be named by the symbols of the parents' strains used in the original mating. They are separated by a period, i.e. B10.D2; this means that B10 originated from C57BL/10SN and D2 from DBA/2J. They can also be designated by using the name of the inbred partner followed by a hyphen and then the name of the differential allele contributed by the donor strain as described.

Numbers and letters in parenthesis are used when several different strains are derived from one initial cross.

There are also symbols that originated for laboratory purposes only but subsequently were used in the literature, i.e. (5M), (HW80), (HW19).

For designation of substrains, the addition of an abbreviation of the laboratory where they originated from is used, e.g.: Sn for Snell and By for Bailey.

When congenic strains differ at nonhistocompatibility loci, designations are used to distinguish the differential loci; e.g. Ea for erythrocyte antigen, Ly for lymphocyte, Thy for thymocyte and Tla for thymus-leukemia antigen.

CONTACT HYPERSENSITIVITY

PS Friedmann, Department of Dermatology, Liverpool University, Liverpool, UK

Contact hypersensitivity is a form of delayed-type or cell-mediated hypersensitivity expressed in the skin. It is initiated by agents/antigens that penetrate through the outer epidermal barrier (stratum corneum) and reach the viable layers of the epidermis. Once the immune system has been activated via the epicutaneous route, topical re-exposure to the relevant antigen elicits an inflammatory response, characterized by edema formation, which reaches a

maximum 48–72 h later. In humans, immunological memory to contact antigens is long-lived, whereas in mice it is usually reported as being transient, lasting only a few weeks.

Functional significance

Contact hypersensitivity is probably important for protective immunity against tumors and microbes,

such as viruses, fungi and parasites (ticks and mites), that invade the skin; however, there is also a response to environmental substances that enter the skin, causing the clinical condition of allergic contact eczema/dermatitis.

Immunobiology

Activation of the immune system via the epicutaneous contact route is dependent upon several factors.

Antigen potency

Some antigens, such as 2,4-dinitrochlorobenzene (DNCB), pentadecylcatechol (urushiol of poison ivy) and diphenylcyclopropenone (diphenylpyrone) are potent and can sensitize all subjects. Many organic compounds and inorganic salts of metals such as nickel, cobalt and chromium are weak antigens and appear only to sensitize some subjects.

Genetic factors

In experimental animals there are clearly genetic controls of immune responsiveness. Thus, inbred guinea pigs of strain XIII can be sensitized with mercury but not chromate or beryllium, whereas animals of strain II can be sensitized with chromate and beryllium but not with mercury. Evidence in humans is less clear-cut. With regard to a strong antigen (DNCB), it seems that everyone can become sensitive but there is a normal distribution of the degree of sensitivity. Family studies have indicated that 'high responder' characteristics are transmitted to children. Studies of HLA linkage in subjects with the propensity to form numerous allergic sensitivities to environmental substances have not found positive evidence of genetic control.

Intact lymphatic drainage

Guinea pigs cannot be sensitized if antigen is applied to islands of skin lacking lymphatic drainage. This is because the early stages of the induction process involve circulation of antigen-bearing cells via the lymphatics to the draining lymph nodes.

Antigen-presenting cells

The epidermis is populated with Langerhans cells. These are leukocytes whose function is presentation of antigens to the appropriate CD4⁺ T lymphocytes. They have long dendritic processes ramifying between the epidermal cells, forming a network likely to be encountered by any organism or antigen which penetrates through the stratum corneum barrier. They are characterized by a formalin-resistant membrane ATPase, a specific cytoplasmic organelle,

the Birbeck granule, membrane antigens including CD1a (T6), class II major histocompatibility complex (MHC) antigens and costimulatory molecules B7-1 and B7-2. Langerhans cells also express various adhesion molecules including E-cadherin, probably necessary for maintaining position in the epidermis, and ICAM-1 and LFA-1, necessary for their migration to the regional lymph node and interaction with T cells.

Induction of contact sensitivity

When epicutaneously applied antigen reaches the Langerhans cells they exhibit signs of activation, as shown by formation of coated pits, appearance of Birbeck granules and loss of surface ATPase activity. During the next 1–4 h antigen-bearing Langerhans cells emigrate from the epidermis and are found in the superficial dermis. They are observed in the lymphatics leaving the site and by 24 h they have reached the draining lymph node. This is the site of interaction with the appropriate antigen-specific CD4⁺ T lymphocytes, which are activated to proliferate. Langerhans cell migration is dependent upon expression of ICAM-1 and LFA-1; mice treated with antibodies against these adhesion molecules fail to develop contact sensitivity and antigen-bearing Langerhans cells fail to reach the regional lymph nodes. Also, evidence suggests that tumor necrosis factor α (TNF α) is an important mediator in stimulation of Langerhans cell migration. The interaction between Langerhans and T cells is via the T cell receptor and antigen–MHC complex and also includes LFA-1/ICAM-1, LFA-3/CD2 and B7-1/CD28 recognition. Additional cytokine signals including interleukin 1 β (IL-1 β) and possibly IL-12 result in differentiation of T cells of the T_H1 type. It is not known to what extent Langerhans cells have to 'process' the antigen. It seems likely that small molecules (haptens), such as DNCB or nickel, may not be processed as they could bind directly to the MHC class II epitopes important for recognition by the T cell receptor. However, evidence is emerging that even small molecules may require metabolic conversion from the prohaptens to the immunogenic haptens.

The sequence of events in which Langerhans cells become activated and leave the epidermis *en route* for the regional lymph nodes appears to be determined at least in part by the antigen. Thus, in contrast to DNCB, a potent antigen, 2,4-dichloronitrobenzene (DCNB), a nonsensitizer, does not induce emigration of Langerhans cells, although it is absorbed through the epidermis equally, and has equal protein-binding properties. It would be inter-

esting to know if DNCB can bind directly to the MHC class II determinants.

Dose-response relationships

As for other physiological systems, the immune system obeys a variety of dose-response relationships. These have been studied in mice and humans using experimental contact sensitivity. Firstly, increasing the concentration of antigen per unit area leads to an increase in the proportion of reactive subjects. Thus, using a 3 cm diameter circle on the forearm, application of 62.5 µg DNCB sensitized 8%, 116 µg sensitized 50% and 500 µg sensitized 100% of experimental volunteers. Not only are more subjects sensitized by increased concentrations of antigen, but also their degree of sensitivity increases linearly with the log of sensitizing dose. By contrast, when concentration is kept constant then, over a wide range, changes of total dose and area of application have relatively little effect. These observations imply that, although the number of Langerhans cells reaching the lymph node is important, it is actually the number of antigen molecules per Langerhans cell that is the major determinant in the activation of specific T cells and their subsequent clonal expansion. Of course, at small areas (less than 1 cm diameter) this ceases to be true and the number of Langerhans cells also becomes critical.

Expression of contact hypersensitivity

When a sensitized animal or person re-encounters an antigen, a series of events occurs which results in the clinically recognizable response of contact hypersensitivity. The response is characterized by vasodilation (erythema), edema of both dermis and epidermis, fibrin deposition and the accumulation of an inflammatory infiltrate of monocyte/macrophages and lymphocytes. Detectable sensitivity reflects the presence of specifically committed CD4⁺ lymphocytes circulating and trafficking through the tissues. Their numbers presumably determine the magnitude of the reaction to antigenic challenge; thus, in fact, subclinical sensitization could be present if the clone of T cells had not expanded sufficiently to leave the lymph node, although 'memory' would have been established. There is clear evidence that such subclinical sensitization can occur. The extent of the clonal proliferation appears to be proportional to the 'drive' from antigen-bearing Langerhans cells, reflected in the increasing degree of reactivity induced by increasing sensitizing doses of antigen.

One of the unanswered questions is whether Langerhans cells have to participate in the secondary pres-

entation of antigen to passing T cells to initiate the response. It seems probable that they are required.

The normal traffic of T cells through the tissues is light and hence the likelihood of the appropriately committed T cell passing by and encountering a few antigen-bearing Langerhans cells in the superficial dermis must be so low that the efficiency and reliability of the system as one of protection would be quite hopeless; therefore there must be initial processes, independent of the physical presence of T cells, which can increase cellular traffic. In rodents, mast cells have been implicated as providing such a mechanism. In humans, the evidence is against the involvement of mast cells. However, the skin 'senses' physical or chemical perturbation, whether by irritant or antigen, by activation of a range of mechanisms aimed at increasing the speed and efficiency of T cell traffic and hence immune surveillance. The mechanisms activated include production of cytokines, upregulation of adhesion molecules on endothelial cells and translocation of Langerhans cells from the epidermis to the superficial dermis.

Cytokines

Within 15 min of application of a contact sensitizer to mouse skin, IL-1β gene transcription is activated in Langerhans cells. Other cytokines including IL-1α, TNFα and chemokines IP-10 and MIP-2 are also upregulated within a few hours. In mice, macrophage migration inhibition factor is also expressed. Some evidence suggests that keratinocytes rather than Langerhans cells are the source of these, and that they are induced by contact sensitizers but not by irritants.

Adhesion molecule expression

Dermal microvascular endothelial cells show upregulation of expression of E-selectin, first observable, 2 h after application of provoking chemicals. ICAM-1 and VCAM-1 increase from 4–6 h onwards and reach a maximum by 24 h. The upregulation of adhesion molecules is seen with both irritants and antigens, and whether individuals are sensitive or 'naive'. These events precede any cellular infiltration. Lymphocyte infiltration is first detectable by 8 h. In individuals sensitive to the provoking substance, a few activated T cells expressing CD25 (IL-2 receptor α chain) are seen at 8 h. After this the reaction builds into a full 'positive response' with heavy infiltration of mononuclear cells. In nonsensitive subjects the various features all subside over the next 12–24 h. Thus, the tissue elements in skin respond to perturbation by activating mechanisms designed to increase the traffic of T cells through the tissues. If an appropriate T cell encounters its target antigen on a Lang-

erhans cell, it is activated to release interferon γ (IFN γ), and a general and nonspecific recruitment of other lymphocytes occurs. This continued accumulation of cells appears to be mediated in large part by IFN γ , as inoculation of rats with a monoclonal antibody to IFN γ reduced by 50–90% the migration of lymphocytes into reaction sites.

Dose–response relationships

As for the induction component of the immune response, so the expression component also exhibits predictable dose–response relationships. Application of a graded series of challenge doses to sensitized subjects elicits a graded series of inflammatory responses. There are several methods for quantifying responses, including measurement of thickness of the edema with calipers or ultrasound, measurement of the redness with reflectance instruments, measurement of the blood flow with a laser Doppler flowmeter, and in experimental animals accumulation of radiolabeled cells can be determined. None of the methods are perfect and various caveats apply to them all. The main one is that at large responses, when edema formation is great enough to cause blistering, all the methods, with the possible exception of radio-labeled cell accumulation, break down.

The mechanisms by which the inflammatory reaction of contact hypersensitivity resolves are not clear. Postulated mechanisms include induction of immunosuppressive cytokines, such as IL-10, or apoptosis of the effector T cell.

CONTRACEPTION, IMMUNOLOGICAL

GP Talwar, International Centre for Genetic Engineering and Biotechnology, New Delhi, India

A major technological advance in the twentieth century was the development of a number of methods to prevent an unwanted pregnancy. Amongst newer methods currently under development are those which employ immunological approaches. Vaccines inducing appropriate immune response have been made, with demonstrated ability to control fertility in experimental animals, including subhuman primates. Extensive safety and toxicology studies have shown the safety and reversibility of some of these

vaccines, and these, with due approval of the drugs regulatory authorities and institutional ethics committees, have undergone clinical trials in humans. Six vaccines have completed phase I clinical trials documenting their safety and reversibility – three vaccines in women and three in men. One vaccine has also successfully completed the phase II trials in women, providing evidence for its efficacy in preventing pregnancy. These trials have established the titers of antibodies and other characteristics (avidity, immuno-

dominant epitopes, bionutralization capacity) to achieve efficacy. Of interest is the application of some of these vaccines in hormone-dependent cancers (carcinoma of the prostate) and lung cancers secreting human chorionic gonadotropin (hCG).

Principle

The rationale behind birth control vaccines is the generation of antibodies and/or cell-mediated immune responses (CMI) against either a hormone or gamete antigen(s) important for the success of reproduction. The production of the gametes in both males and females is critically regulated by hormones. A cascade of hormones is involved, starting from the gonadotropin-releasing hormone (GnRH or LHRH) secreted by the hypothalamus. This decapeptide hormone, common to both males and females, stimulates the production and secretion of the two gonadotropins follicle stimulating hormone (FSH) and luteinizing hormone (LH) by the pituitary. These act in concert on the gonads to generate eggs or sperm from the ovaries or the testes, respectively (Figure 1).

Figure 1 Hormones involved in the production of gametes and sex steroids. Antibodies inactivating one or more of these hormones would block fertility. hCG secretion from the embryo starts at the preimplantation stage. It has a role in nidation (initiation of pregnancy) and in its sustenance for 7 weeks by production of progesterone from ovaries.

The fertilized egg also makes the hormone hCG, secretion of which by the preimplantation human embryo is detectable in culture following *in vitro* fertilization prior to transfer to the uterus. Evidence points to a crucial role of this hormone in implantation, and antibodies inactivating hCG intercept implantation. Following implantation, the amount of hCG secreted increases sharply until 7–9 weeks of pregnancy, after which it declines to a lower level and stays so throughout pregnancy in humans. A second important biological role of hCG is in sustenance of the ovarian corpus luteum and in continued production of progesterone for the first 7–9 weeks, after which the placenta takes over the production of progesterone. hCG thus has a dual role, in establishment of pregnancy (implantation of the embryo into the endometrium) and in its sustenance for at least 7–9 weeks. Antibodies against hCG can prevent the establishment of the pregnancy if these are pre-existing in the circulation by virtue of active immunization. Antibodies given passively at the postimplantation stage but during the first 7 weeks of pregnancy have been shown, in baboons, to terminate pregnancy and thus act as an abortifacient.

Vaccines under development

Antibodies inactivating any one or more of the hormones depicted in Figure 1 would theoretically result in impairment of fertility. However, intervention in the action of LHRH would also block the production of sex steroids. This may be desirable for the control of fertility of animals (dogs, cats, animals raised for meat) but not acceptable for contraception in humans. It should be noted, however, that LHRH secretion remains suppressed during lactational amenorrhea. Family planning advocates recommended spacing of children by breast-feeding, which in ancient societies was a 'natural' method of stopping ovulation. But to keep LHRH, and thereby ovulation, suppressed, the breast suction must take place frequently during the day and the night, a *modus vivendi* not easily practicable for modern women. An alternative would be to inactivate LHRH by circulating antibodies by immunization with the LHRH vaccine to prolong lactational amenorrhea and interchild interval. LHRH vaccine is thus conceivable as a postpartum vaccine and can have a special niche in the contraceptive array. Fraser and colleagues have reported the block of ovulation in breast-feeding women for 9–11 months by using an LHRH agonist.

Blocking ovulation has been the principal strategy for contraception in oral pills and contraceptive steroids delivered as injections. Most of them inhibit the

production of the normal sex steroids by the woman, and their deficiency is made good by the synthetic hormonal analogs administered. It will be counter-productive to have a vaccine which would also demand synthetic hormones as implants for retention of libido and other metabolic functions. Hence an LHRH vaccine will not in general be suitable for contraception, other than in the period following delivery of the child and during lactation where physiologically LHRH secretion remains inhibited.

In contrast, if immunological interception is targeted at hCG, the normal hormonal cascade would stay intact. The woman would ovulate and produce normal levels of sex steroids. The intervention occurs only following fertilization at the preimplantation stage. These were amongst the considerations that led to hCG being the preferred target for the first type of birth control vaccines devised.

Tables 1 and 2 summarize the many vaccines being made. It will be noted that the most advanced vaccines are those directed against hormones. Four

vaccines are directed against hCG, two against LHRH and one against FSH.

A large number of vaccines are being made against sperm and egg antigens; the nature and status of these are summarized in Table 2. Additionally, one vaccine aims to block the uptake of an essential vitamin for embryo development.

Antibody response to 'self' hormones – need for carriers

β hCG or LHRH used as vaccines in humans would not by themselves induce appreciable antibody responses, especially when employing permissible but relatively weak adjuvants such as alum. Their immunogenicity is substantially enhanced, however, by linkage with an immunogenic carrier. Tetanus toxoid (TT), diphtheria toxoid (DT) and cholera toxin chain B (CTB) have been used for this purpose with successful results. They increase the immune response against the hormone and at the same time they generate antibodies against the carrier, which

brings in an immunoprophylactic benefit to nonimmunized individuals. TT and DT are good carriers. However, repeated immunization with conjugates containing these carriers can cause hyper-responsiveness to the carrier, shutting off the immune response to the attached hormone. In humans, about 11–15% of subjects developed carrier-induced immunosuppression upon repeated use of TT-containing conjugates. The suppression could, however, be overcome by presenting the ligand on an alternative carrier, such as CTB. As has been shown by Eli Sercarz and colleagues, a protein such as lysozyme has both stimulating and inhibitory determinants. Proteins have epitopes stimulating T and B cells. A number of T helper determinants have been mapped in viral, bacterial and parasite coat proteins. Their judicious choice can enable communication with the entire major histocompatibility complex (MHC) spectrum, so that vaccines constructed using these peptides as carriers can elicit immune responses in individuals of different genetic background. Experimentally it has been found that the heterospecies dimer (HSD) hCG vaccine linked to peptides containing three different T cell epitopes induces as good, if not higher, antibody responses than TT or DT conjugates in mice of different genetic strains.

Vaccines in clinical trial and their current status

The hCG vaccines

Three vaccines have been developed against hCG for use as antifertility agents. One of them employs the carboxy-terminal 37 amino acid peptide (CTP) of the β subunit of hCG, another the entire β hCG, and the third hCG vaccine is an HSD composed of the β -hCG associated noncovalently with the α subunit of ovine LH. The ability of the subunits to combine is conserved across species. In fact, the HSD has a higher steroidogenic potency than the homospecies dimer hCG. The α peptide of another species would be expected to enhance immunogenicity of the vaccine in humans. Data in Table 3 summarize the highest antibody titers attained in humans using the three types of hCG vaccine which have undergone phase I clinical trials. HSD is indeed the most immunogenic of the three constructs. Another feature of this vaccine is the higher bionutralization capacity of the antibodies that it generates. Different epitopes in a macromolecular hormone antigen induce antibodies with variable capacities for inactivating the hormone. High titers of antibodies (as determined by radioimmunoassay) obtained against the CTPs of

β TSH or β hCG using strong adjuvants such as Freund's complete adjuvant do not always inactivate the bioactivity of the parent hormone, possibly due to the poor avidity of these antibodies. The affinity of hCG for its ovarian receptors is of the order of 10⁹. Antibodies ten times less avid may not be able to prevent hCG binding to its receptors.

The lead work on the β hCG CTP vaccine was carried out by Vernon Stevens in Ohio. Phase I clinical trials of this vaccine were conducted by Warren Jones in Australia with the support of the WHO. The vaccine was employed at different doses in 20 women who had elective tubal ligation, another ten women served as vehicle controls. No significant side-effects ascribable to immunization were reported by the investigators. However, this vaccine could not proceed to phase II efficacy trials because it produced unacceptable side-effects in the first seven subjects enrolled in Sweden. Its efficacy in humans thus remains untested. Dirnhofer and colleagues have cast serious doubts on the efficacy of this vaccine.

The β hCG-TT vaccine was initially conceived and developed by Talwar and coworkers in New Delhi. Its early phase I trials were conducted in India. The same vaccine was taken up by the International Committee on Contraception Research of the Population Council and two series of phase I clinical trials were carried out, the first in Finland (Tapani Luukkainen), Sweden (Elof Johansson), Brazil (Elsimar Coutinho) and Chile (Horacio B. Croxatto), and the second in the Dominican Republic (Vivian Brache), Finland (Pekka Latteenmaki) and Chile (Horacio Croxatto). Both the trials in India and in other countries demonstrated the safety of the vaccine and lack of side-effects. Sequential bleeds provided data on the levels of FSH, LH, estradiol and

progesterone, which remained normal with ovulatory cycles. In all centers the antibodies declined to near zero levels in the course of time in the absence of boosters, thus indicating the reversibility of the vaccine.

The HSD vaccine was made by Talwar and colleagues with the aim of further improving the immunogenicity of the β hCG-TT vaccine (Table 3). After confirming its safety, lack of side-effects and noninterference in ovulation and regularity of menstrual cycles, phase II efficacy trials were conducted with this vaccine in 148 women of proven fertility (at least 2 children) who were sexually active; 119 of them (80%) made antibodies above 50 ng ml⁻¹ bionutralization capacity, a threshold fixed for determining the effective titers. Women had the option of leaving the trial or taking booster injections as and when antibody titers declined towards or below 50 ng ml⁻¹. Only one pregnancy occurred in 1224 cycles, showing the high efficacy of the vaccine in preventing pregnancy as long as the titers remained above 50 ng ml⁻¹. The ability of antibodies to deter pregnancy was also confirmed by postcoital tests. The block of fertility was reversible. On decline of antibody titers below 35 ng ml⁻¹ conceptions readily occurred (Figure 2). Those desirous of having another child, after a gap with the use of the vaccine, have carried pregnancy to term and have given birth to normal babies.

Optimization of the HSD The HSD-hCG vaccine has provided the scientific foundations of a birth control vaccine which prevents pregnancy without impairing ovulation or deranging menstrual regularity. Its characteristics render it usable at all stages of reproductive life. It is, however, not yet ready as a product. Further optimization of the vaccine is

Figure 2 A representative subject showing the kinetics of anti-hCG titers (●—●), menstrual events (top squares) and the period of protection from pregnancy (solid line). This lady of 30 years of age with two live children and one elective termination of pregnancy was among the 119 subjects on which the efficacy of the HSD vaccine was determined in phase II trials. The graph also shows the reversibility of the vaccine with return of fertility in the cycle when her antibody titers declined to less than 5 ng ml⁻¹ bionutralization capacity. (Reproduced from Talwar *et al* (1994).)

necessary to enhance the percentage of high responders making antibodies above 50 ng ml⁻¹. The present vaccine is adsorbed on Alhydrogel. As more potent adjuvants get regulatory approval, their use may facilitate the enhancement of antibody titers. Another strategy will be the substitution of the DT/TT by T cell determinants communicating with the entire MHC spectrum.

We have determined the joint ability of three T cell epitope peptides derived from circumsporozoite protein of *Plasmodium falciparum*, respiratory syncytial virus and purified protein derivative (*Mycobacterium tuberculosis*) to generate higher titers of antibodies in seven genetic strains of mice than those obtained with DT as a carrier for the HSD. Encapsulation of the vaccine in biodegradable microspheres can also add to the immunogenicity and at the same time enable the delivery of multiple doses of the vaccine at a single contact point. To make the vaccine at low cost and in a reproducible manner on a large scale, it will be necessary to use recombinant DNA technology. β hCG has been expressed with and without fusion proteins in vaccinia as a naturally glycosylated peptide, in baculovirus with higher yield but somewhat different glycosylation, and in *Escherichia coli* and *Vibrio cholerae* with still higher yield unglycosylated. Live recombinant vaccines employing attenuated pox viruses,

adenoviruses, salmonella or BCG as vectors may offer very low cost vaccines generating a protective immune response over long periods. Ivan Roitt and colleagues have employed recombinant technology to make a mutant of β hCG lacking in reactivity with a panel of anti-hLH antibodies but preserving the immunoreactivity with monoclonal antibodies recognizing hCG.

Applications of the hCG vaccine in hCG-synthesizing lung cancers Although hCG is known mainly as a trophoblast product and its increased levels in serum or urine are employed as a diagnostic test for pregnancy, its synthesis and secretion has also been reported in about 30 different types of cancers. The function, if any, of hCG or its subunits made by tumor cells is unknown. Debajit Biswas and coworkers at Harvard Medical School observed that Chago cells derived from a human lung cancer produced hCG α chain, which promoted the growth of these tumor cells. Antibodies reacting with the hCG subunit, or antisense RNA, caused inhibition of cell proliferation. Cell clones derived from lung cancer make either isolated α or β chains or whole hCG. Antihormonal subunit antibodies given passively to nude mice bearing tumors formed from Chago cell implants have been shown to cause necrosis of the tumor. When tumor cells were exposed to antibodies from the time of implantation, growth was inhibited in a dose-dependent manner, with total absence of tumor growth at high doses of antibody.

Given that no effective chemotherapy is at present available for hCG-synthesizing lung cancers, regulatory permission was given in Mexico to carry out clinical trials with the hCG vaccine in three patients characterized on the basis of clinical manifestations backed by radiography, histopathology and serum β hCG levels. All three patients tolerated immunization with the vaccine well. The serum β hCG declined to near zero levels after immunization. No further metastasis occurred during 2.5 years of follow up and the Karnofsky index improved for one of the patients. These studies clearly need to be extended to a larger number of individuals in order to draw any conclusions regarding the efficacy of the hCG vaccine in such patients.

LHRH vaccines

Two vaccines against LHRH are in clinical trials in carcinoma prostate patients. The vaccine made by Rose Marie Thau, Y. Tsong and colleagues at the Population Council in New York has TT tagged at the N-terminus of the decapeptide, whereas the vaccine developed by Talwar and coworkers in New Delhi employs a modified LHRH with the glycine at

position 6 replaced by D-lysine. This is linked through a spacer to DT.

The rationale employed in the New Delhi vaccine is to preserve the natural conformation of the LHRH, where N- and C-terminal amino acids are proximal to each other with a bend in the middle of the molecule. Substitution of glycine at position 6 by D-lysine stabilizes this conformation and also slows the catabolic degradation of LHRH by the enzyme cleaving at glycine 6.

Both vaccines are immunogenic in rodents, have passed through toxicology studies, and are in clinical trials. The Population Council vaccine (LHRH-1-TT) was tried in four orchietomized men to determine the immunogenicity of the vaccine, its reversibility and immediate and delayed side-effects. These studies have shown that the vaccine was well tolerated and that although there was a large variability in antibody titers between the four subjects, they all made antibodies to LHRH. In order potentially to use this vaccine for male fertility control, these investigators have also carried out studies in rodents to assess the dose of androgens required to restore libido without reversing the inhibition of spermatogenesis.

The New Delhi LHRH vaccine (LHRH-6D-Lys-DT) has undergone phase I/phase II clinical trials in advanced stage patients with metastatic carcinoma of the prostate. In one study 24 patients received either 200 or 400 µg LHRH equivalent per injection. No ill-effects of immunization were reported in any of the studies despite the advanced age of the patients and their low health status. All the subjects made antibodies against LHRH and many, but not all, produced sufficiently high titers to cause depression of testosterone to castration levels. Prostatic-specific antigen serum levels declined significantly. Ultrasonography showed shrinkage of prostatic mass. These studies indicate the potential of this vaccine in prostatic hypertrophy as an inexpensive alternative to the LHRH synthetic analogs. Immunotherapeutic use could extend to endometriosis and precocious puberty, however clinical trials remain to be undertaken in these conditions.

The LHRH vaccine, with stronger adjuvants, also has applications for reversible fertility control of domestic pets. Given that this decapeptide hormone is identical in males and females, the same vaccine could be used in male and female animals.

FSH vaccine

This vaccine was conceived by Moudgal and colleagues for male fertility control on the basis of the requirement of FSH for spermatogenesis in primates. Passively administered antibodies to FSH caused a

significant reduction of bonnet monkey sperm count without affecting testosterone. Ovine FSH was chosen as the antigen, which induced in monkeys both monkey and human FSH cross-reactive antibodies of high affinity. Immunization caused a reduction in sperm count and the fertilizing capacity of the remaining sperm was significantly reduced. A study conducted in three laboratories demonstrated that 25 out of 27 monkeys immunized with ovine FSH became infertile. Fertility was regained on decline of antibodies.

After toxicology studies and regulatory ethical approval, a phase I study with this vaccine was initiated in 19 adult human males in three centers in India. Antibodies were made by all of the subjects but the titers of antibodies reactive with human FSH were low. The mean avidity of the antibodies was also an order of magnitude lower than in the previous studies in primates. Vaccination was, however, well tolerated. There were variations in the levels of pituitary hormone such as prolactin in some subjects. No significant effect of immunization on sperm count was noted, presumably owing to the low titers of antibodies or an insufficient duration of the study. Repeat phase I trials are planned with the vaccine employed at different doses.

CONTRASUPPRESSION

Douglas R Green and **Patrick M Flood**, La Jolla Institute for Allergy and Immunology, La Jolla, California, USA

Contrasuppression refers to any immunoregulatory activity that facilitates immune responses by interfering with suppressive influences, without otherwise helping or augmenting the response. While this is the original definition given by RK Gershon who coined the term, it came to refer more specifically to a regulatory T cell activity, i.e. the function of T contrasuppressor cells. As is true for other regulatory T cells (e.g. suppressor T cells), the existence of contrasuppressor T cells as a discrete functional population is controversial.

In this brief overview, the concept of contrasuppression is reviewed from two perspectives. The first is an uncritical view of the original literature on the phenomenon; the second is from the standpoint of current thinking on the functions of T cells. From the outset, however, the reader should be aware that while most of the observations on contrasuppression have eluded biochemical and molecular characterization, they were described from a number of laboratories and continue to be reproduced. Although this state of affairs demands that all of the conclusions regarding contrasuppression be treated with caution, this regulatory phenomenon exists. Questions concerning whether or not contrasuppression is *important* are discussed in more detail below.

Background

The study of immunoregulatory T cells began in 1970, with the experiments of Gershon and Kondo, showing that T cells can adoptively transfer some forms of immunological tolerance. Work from a large number of laboratories focused on such suppressor T cells and their soluble mediators ('suppressor factors'). During the 1970s, complex regulatory pathways were described in which different T cell subpopulations induce, transduce and effect antigen specific suppression of immune responses. Intensive study of the regulatory cells and factors implicated their involvement in a range of immunologic phenomena.

Based on the idea that tolerance is due to active suppression of immunity and on the observation that cross-reactive antigens can sometimes break tolerance, in 1974 Gershon predicted that there is an immunoregulatory activity that functions to interfere with suppression. In 1981 his laboratory published a series of papers describing such an activity, and since then T cells with contrasuppressive activity have been identified in a number of different systems. In all cases, contrasuppression allows immune responses to proceed in the presence of demonstrable, active suppression.

Research on suppressor and contrasuppressor T

cells suddenly slowed in the mid- to late-1980s for several reasons. Most significantly, efforts to fully characterize antigen specific regulatory T cell factors uniformly failed, despite encouraging results early on. A second confounding problem was I-J, a marker that was associated with many regulatory T cells (including T contrasuppressor cells). Molecular analysis of the region of the major histocompatibility complex (MHC) to which I-J was mapped revealed an absence of any structural MHC gene encoding the molecule. These and other problems cast the study of regulatory T cells in a poor light. Nevertheless, several groups continue to successfully study these regulatory phenomena with interesting results, and therefore an open-minded outlook is warranted.

Characteristics of cells with contrasuppressive activity

The single discriminating characteristic of contrasuppressor T cells is their function: the ability to interfere with immune suppression *without* providing active help. Depending upon the system studied, this functional activity may appear to be antigen specific or nonspecific. Contrasuppressor cells act prior to suppressor cells, i.e. contrasuppressor cells do not restore responsiveness to previously suppressed cells, but rather interfere with inhibition. In some systems, contrasuppression has been shown to render target cells (helper T cells or B cells) resistant to subsequent suppressive influences. However, this does not rule out the possibility that some contrasuppressive effects are mediated by direct inhibition of suppressor functions in some systems.

In general most murine cells with contrasuppressive activity are Thy-1⁺ and where examined, human and rodent contrasuppressor cells have also been found to be CD3ε⁺. The cells are therefore likely to bear T cell receptors. In addition, most contrasuppressor cells are bound by the *Vicia villosa* lectin, but while this trait distinguishes them from other functional T cells (such as helper T cells) it does not provide a unique marker. It is important to note therefore, that binding of this *N*-acetyl-D-galactosamine-specific lectin does not *define* contrasuppressor cells, but rather provides a convenient means of enriching cells with functional contrasuppressive activity.

Contrasuppressive T cells are phenotypically heterogeneous with respect to CD4 and CD8. Functional contrasuppressor cells may be CD4⁺, CD8⁺, or CD4⁻8⁻, depending upon the system studied and the cellular interactions involved. Where examined, CD8⁺ T contrasuppressor cells require the presence of a population of CD4⁻, CD5^{hi}, CD8⁺ T cells in order to mediate contrasuppression. Therefore, such

CD8⁺ cells have been designated as inducer cells, or Tcsi. In contrast, where examined, CD4⁺ T contrasuppressor cells have been found to act without a requirement for an intermediary (or 'transducer') population, and have therefore been designated as effector cells, or Tcse. The relationships between Tcsi and Tcse have not been rigorously explored.

Little is known about the T cell receptors of contrasuppressor cells. In one series of studies, a population of CD3⁺, CD8 intraepithelial cells from murine intestine were found to have contrasuppressive activity *in vitro* and *in vivo*. Immunoprecipitation from the cell surface suggests that this population of T cells express the γδ T cell receptor (TCR). Other contrasuppressor cells are likely to express the αβ TCR, as has been observed in a T cell hybridoma with contrasuppressive activity.

One marker that has been associated with contrasuppressor T cells is 'I-J'. As mentioned above, the nature of I-J is controversial. Nevertheless, antisera and monoclonal antibodies with anti-I-J activity have been shown to remove cells with contrasuppressive activity in many different systems.

It is important to note that since contrasuppression is defined by function and not by cell phenotype, there is little evidence to suggest that contrasuppressor T cells represent a discrete T cell population. Although this remains a possibility, it is equally likely that contrasuppression represents a functional property of many T cells that may have other functions as well.

Experimental studies of contrasuppression

In order to study contrasuppressive effects, it is necessary (by definition) to employ a system involving active suppression of a measurable immune response. This necessarily complex situation is one source of the problems associated with this phenomenon (see below). Nevertheless, contrasuppression has been demonstrated in a number of different systems, both *in vitro* and *in vivo*.

In vivo studies of contrasuppression often take advantage of protocols for the induction of antigen-specific tolerance. For example, antigen-coupled spleen or peritoneal exudate cells, injected intravenously, induce an active state of tolerance that is blocked by the administration of T cells with contrasuppressive function. Such contrasuppressor cells may act either antigen specifically or nonspecifically, depending upon the source of the cells. Tolerance induced by oral administration of xenogeneic red blood cells is similarly blocked by contrasuppressor T cells derived from gut-associated lymphoid tissue.

In this system the contrasuppressive effect favors immunoglobulin A (IgA) responses, and the contrasuppressor cells appear to bear $\gamma\delta$ T cell receptors (as determined by immunoprecipitation of the receptor on the enriched functional population).

Studies of the regulation of the adoptive transfer of contact hypersensitivity have also demonstrated the effects of contrasuppression *in vivo*. T Cells from tolerized animals inhibit the ability of T cells from immune animals to adoptively transfer immunity into naive recipients, and contrasuppressor T cells block this inhibitory effect. These hapten-specific contrasuppressor T cells have been generated by injection of haptenated Langerhans cells, haptenated murine IgG, or haptenated peritoneal exudate cells treated with antihapten antibody of the IgM, IgG1, or IgG3 subclasses. In each case *V. villosa* lectin-adherent T cells from the treated animals were found to be incapable of adoptively transferring immunity, but capable of blocking suppression of immune T cells. Further, these contrasuppressor T cells were found to release a cell-free factor that renders immune T cells resistant to suppression, either by inhibitory T cells or by the environment of a tolerized recipient.

A murine model of autoimmune nephritis has implicated contrasuppression in the development of autoimmunity. In the nephritis-prone kdkd mutant, T cells capable of contrasuppressing delayed-type hypersensitivity to renal tubule antigen appear with onset of autoimmunity. When these *V. villosa* lectin-adherent T cells were mixed with wild-type spleen cells and injected into kidney capsules, destruction of tubules and mononuclear infiltration followed. This was not observed with either population alone, nor with spleen cells plus lectin-nonadherent (and noncontrasuppressive) T cells. One interpretation of these results is that antitubule immunity is normally suppressed by an active mechanism, and that contrasuppressor cells from the autoimmune mice are capable of interfering with this suppression.

Another series of studies suggest that contrasuppressor T cells may be important in some forms of tumor immunity. Two fibrosarcoma cell lines, one regressive and one progressive, have strikingly different effects when haptenated and injected into animals. The haptenated progressor line was observed to induce T cells capable of suppressor hapten-specific responses *in vivo*, while the haptenated regressor line instead induced hapten-specific contrasuppressor cells. These effects were studied using the contact hypersensitivity systems mentioned above. The contrasuppressor T cells induced by the regressor line displayed markers common to such cells, and released a cell-free, hapten-specific, contrasuppress-

ive factor. The cells were used to generate a T cell hybridoma that constitutively produces this factor. Injection of hapten-immune mice with either the *in vivo* generated contrasuppressor cells or with the hybridoma-derived factor rendered these animals immune to haptenated progressor tumor cells (that otherwise grow in and eventually kill naive or hapten-immune animals).

A number of studies have characterized contrasuppression *in vitro*, including human contrasuppressor cells. As in the murine system, human contrasuppressor T cells were found to be adherent to the *V. villosa* lectin and to interfere with active, T cell-mediated inhibition of immune responses. The induction of these cells was found to be dependent upon antigen dose (the optimum dose depending upon HLA-DR type) and they have been shown to block suppression of both antibody responses and T cell proliferation *in vitro*.

Problems with contrasuppression

As mentioned above, the phenomenon of contrasuppression is controversial for a number of reasons. One of the most important reasons lies in the fact that contrasuppression is defined by its effects on suppression. However, the mechanisms of suppression (let alone contrasuppression) are unknown.

Regulatory cells are by their nature a property of the immune system whose activity can only be measured as a function of the immune activity of other cells. This complexity carries special problems of completely characterizing the activity of even a single component of these interactions. On the other hand, the demonstration of this functional activity *in vivo*, and the common features of the cells responsible for contrasuppressive function, suggest that this may be an important, if poorly understood phenomenon.

No known lymphokine or other well-defined molecule, either alone or in combination with other molecules, can fully account for the phenomenon of contrasuppression. The suggestion that at least some contrasuppressor cells release antigen-specific contrasuppressor factors presents additional problems, since no such factor (suppressor or contrasuppressor) has been well characterized. The alternative, that some contrasuppressor T cells act via the release of one or more lymphokines has not been fully explored. Thus the molecular basis of contrasuppression in any system is unknown.

It is unlikely that the problems associated with the study of contrasuppression will be solved in the near future. It is likely, however, that the phenomenon will return in a different guise as we learn more

about the workings of the immune system as a whole.

COOPERATION, MECHANISMS OF CELLULAR

Theodore J Yun, Department of Microbiology, University of Washington, Seattle, Washington, USA

Edward A Clark, Departments of Microbiology and Immunology, University of Washington, Seattle, Washington, USA

Various pathogens, ranging from viruses to helminths, can invade the host by a number of pathways, and usually the pathogen is cleared through an orchestrated immune response. Moreover, protection from a repeat infection is provided by a memory response, which, relative to the primary response, is rapid and highly specific. This coordination of multiple effector cells relies on communication between cells of the immune system and cells in their environment. Many of the components involved in cellular cooperation are molecules that are produced by the cells which bind to receptors on other cells. We can roughly divide these components into two major categories: membrane-bound and secreted. This discussion will focus on certain membrane-bound molecules and their influence on the immune response.

The immune response has many examples of cellular cooperation. Tissues secreting chemokines alert the immune response to areas of damage and potential pathogen invasion. Adhesion molecules, such as selectins and integrins, present on cells of the tissues and leukocytes mediate cellular homing, margination and migration. Once these cells are in the site of damage, membrane-bound receptors in conjunction

with secreted cytokines activate immune cells and enable them to develop a potent effector reaction. As a prototypical example of cellular cooperation in the immune response, we will focus on germinal center (GC) development in the response to T cell dependent antigens. Consider the formation and maintenance of GCs developed during primary immune responses. This entire process relies upon communication between multiple cells, including T cells, B cells, interdigitating dendritic cells (IDCs), germinal center dendritic cells (GCDCs) and follicular dendritic cells (FDCs). Resting T cells interact with activated IDCs presenting antigen initially captured from local sites of damage, such as mucosal or epidermal tissues. B cells, also activated through antigen encounter, are further helped along their maturation pathway by interaction with the T cells. The activated B cells undergo affinity maturation by interaction with antigen bound on FDCs. Early in this process, somatic hypermutation of B cell antigen receptors (BCRs) generates novel specificities, some of which have greater affinity for antigen. Antigen uptake mediated by the BCRs, followed by processing and presentation in class II major histocom-

patibility complex (MHC) molecules to the cognate T cells results in T cell help that propagates the B cell. B cells bearing novel specificities which have lost affinity to antigen, or have acquired affinity to another antigen, must be eliminated. Through types of receptor-mediated 'reciprocal dialogues' in the GC, lymphocytes can be induced to proliferate and differentiate, or, equally as important, can be instructed to undergo programmed cell death.

Membrane-bound molecules are critical for lymphocyte activation

Lymphocyte activation by a foreign antigen is the initial step in the humoral response against T-dependent antigens. We generally regard activation of a resting B or T cell as a multistage process involving multiple signals transduced through membrane receptors. This model is based on the historic two-signal model initially proposed by Bretscher and Cohn. For example, a T cell requires costimulation in addition to the signal it receives from its antigen receptor binding to its cognate MHC/foreign antigen complex. If the T cell fails to receive costimulatory signals, the model proposes that the cells cannot be activated. Similarly, multiple signals are required to activate B cells. Some studies have suggested that resting lymphocytes which receive one signal are rendered unresponsive, or anergic. Characterization of single molecules which synergize with antigen receptor signals to activate lymphocytes has remained elusive. This fact emphasizes the dialogue of multiple receptor signals between cells during lymphocyte activation. The following discussion will focus primarily on the recent body of evidence dealing with specific membrane-bound coreceptors that appear to be necessary for activating or downregulating T cells or B cells. Two receptor/counter-receptor families will be discussed: members of the immunoglobulin superfamily (IgSF), and members of the tumor necrosis factor receptor (TNF-R) and tumor necrosis factor (TNF) family. The IgSF molecules, CD80/CD86 (B7-1/B7-2) interact with two distinct counter-receptors, CD28 and CD152 (CTLA-4), which either activate or downregulate T cells, respectively. Currently, novel members of the TNF-R/TNF family are rapidly being characterized. Functionally, these molecules appear to have an important role in determining cell fate, as exemplified by CD40 and CD95 (Fas).

CD80/CD86: CD28/CD152 interactions have dual roles in regulating lymphocytes

CD80 and CD86 are members of the IgSF. They are approximately 60 kDa in size. Both bear similar

overall structure, with two extracellular Ig-like domains, a transmembrane domain and cytoplasmic tail; however, at the amino acid level they have only 25% homology to each other. Interestingly, the cytoplasmic domains of CD80 and CD86 barely resemble each other, which suggests different signaling functions.

Consistent with their role as critical costimulatory molecules in the initial steps of T cell activation, CD80/86 are expressed on antigen-presenting cells (APCs), such as IDCs, GDCs, Langerhans cells and activated monocytes. The expression of these molecules can be induced upon activation of other APCs. In particular, CD80/86 are upregulated on B cells by cytokines, such as interleukin 4 (IL-4), or by receptor cross-linking of the BCR, MHC class II or CD40. There are differences in expression between CD80 and CD86, although the functional relevance of this is unclear. For example, during activation of B cells, CD86 is expressed more rapidly than CD80.

While CD80 and CD86 have both been demonstrated to bind their counter-receptors CD28 and CD152, there is suggestive evidence that CD80 and CD86 may have different biologic functions. This variance may, in part, be due to differences in ligation of receptor – such as variation in binding kinetics and avidity – and in induction and expression of CD80 and CD86. For example, in the GC, expression of CD80 and CD86 differs between B cell centroblasts and centrocytes. Ectopic overexpression of CD86 results in deletion of B cells by CD28⁺ T cells which can be prevented by introduction of hen egg lysozyme (HEL)-specific B cells, T cells and the HEL antigen. This suggests that CD86 can play a role in elimination of nonspecifically activated B cells. Comparing immune responses of mice which are CD80^{-/-}CD86^{+/+}, CD80^{+/+}CD86^{-/-} or CD80^{-/-}CD86^{-/-} suggests that either molecule is required to mount a humoral response, depending on the route of antigen administration. Either CD80 or CD86 is sufficient for immune responses to soluble antigen inoculated intradermally. However, CD86, but not CD80, is required for antigens inoculated intravenously.

CD28 costimulates T cells

CD28, one of the two known ligands for CD80/86, is also a member of the IgSF. It is expressed on the surface as a 90 kDa, disulfide-linked homodimer. CD28 is mainly expressed on T lineage cells, including thymocytes, but may also be found on plasma-blasts. The level of expression varies, depending on the lineage and the activation state. Upon activation of a mature T cell, either by mitogen or by cross-linking of the TCR, the expression of CD28

increases. However, following this upregulation, ligation of CD28 by its counter-receptors apparently induces a transient negative feedback to downregulate expression and render the cells unresponsive to CD28 signaling.

CD28 usually transduces a positive signal that promotes proliferation of TCR-stimulated T cells. Studies demonstrating its importance in the initial steps of T cell activation include *in vivo* blockade of its counter-receptors, CD80 and CD86, and genetic deletion of CD28 expression. In addition to its costimulatory role, CD28 ligation can enhance the production of various cytokines, such as IL-2, IL-4 and IL-10. CD28^{-/-} mice have reduced IgG responses to T-dependent antigens and reduced GC formation. Taken together, these observations suggest that CD28 is critical for T cell-dependent antibody responses. Responses generally attributed to T_H1 cells remain. In some experimental systems, CD28 ligation rescues T cells from anergy. CD28 may also play a role in prolonging an activated T cell's fate and initiating its differentiation into the memory phenotype. In the absence of CD28 signaling, activated T cells do not survive as long. CD28 costimulation can upregulate the expression of Bcl-xL, a protein that prevents CD95-induced apoptosis.

CD152 downregulates T cells

In addition to their role of providing costimulation to T cells, CD80 and CD86 may also play a role in downregulating the immune response. A second counter-receptor, CD152, binds to both CD80 and CD86 with approximately 20-fold higher affinity than CD28. This molecule has significant sequence identity to CD28. The *cd152* and *cd28* loci are located on the same chromosome and share similar intron/exon structure. They probably arose from a gene duplication. CD152 is also a member of the IgSF of molecules.

CD152 is expressed on most activated T cells. Its cell surface expression pattern is unusual in that it appears to be regulated post-translationally. At the mRNA level, CD152 transcription is detectable hours after T cell stimulation; however, the protein is retained intracellularly. Truncation or replacement of the cytoplasmic region of CD152 increases its cell surface expression. Temporally, the expression of CD152 is upregulated during a period of transient downregulation of the CD28 molecule expression.

CD152 can function as a negative regulator of the immune response. Antibody blockade of this receptor enhances T lymphocyte proliferation and delays apoptosis, suggesting a negative regulatory function for CD152. The generation of CD152-deficient mice has confirmed this. These mice have massive lympho-

proliferation defects and multiorgan destruction. This lymphoproliferation in CD152^{-/-} mice appears to be antigen driven. An accumulation of lymphocytes in secondary lymphoid organs is noticeable about 1 week after birth. By 4 weeks, the number of lymphocytes in these organs is up to five times the number found in wild-type controls. Also by this time, most organs are infiltrated by lymphocytes. These observations, taken together, suggest that CD152 plays a critical role in the regulation of autoreactive T cells, as well as in the downregulation of activated T cells.

TNF/TNF-R receptor/counterreceptors influence cell fate

CD154:CD40 ligation costimulates B cells

CD154 (CD40L, gp39 or T-BAM) is a member of the TNF gene family, which includes TNF, CD30L, FasL and TRAIL. Similar to other members of this family, it is a type II membrane protein of 30 kDa in size. CD154 can be detected on activated T cells, monocytes, natural killer (NK) cells, human mast cells, basophils, some DCs and some CD8 T cells. CD154 is not detectable on resting T cells. Upon ligation of the TCR, CD154 becomes transiently expressed. The expression of CD154 on T cells is consistent with its importance of providing help to B cells during a humoral response to T-dependent (TD) antigens. CD154 expression on DCs can also promote B cell maturation. The function of CD154 on other cell types is currently unknown.

Trimeric CD154 binds to and cross-links CD40. CD40 is expressed on all APCs, such as DCs, Langerhans cells, macrophages and B cells. It is also found on basal epithelial cells, FDCs, endothelium and thymic epithelium. CD40 is approximately 45–50 kDa in size and is a member of the TNF-R family, which includes CD95, TNF-RI, TNF-RII, CD30, CD27, TRAIL-R, NGF and 41-BB. These proteins are characterized by a cysteine-rich extracellular domain and a unique cytoplasmic domain. Currently, it is generally believed that regions in the cytoplasmic domain mediate the receptor's association with other proteins that transduce signals from the receptor. One molecule with which CD40 has been shown to associate is termed TRAF3. This protein has a number of putative DNA-binding motifs; however, its function is currently unknown. It may mediate activation of MAP kinase family members, because stimulation of CD40 causes activation of NF- κ B, SAPK (JNK) and p38 MAP kinase pathways.

The importance of the CD154/CD40 interaction in the generation of a humoral response is highlighted by a naturally occurring congenital defect of

CD154 in humans, and is paralleled by the CD154-deficient mouse. The human disease, X-linked hyper-IgM syndrome, is signified by lack of IgG, IgA and IgE isotypes, GC formation and memory B cells in patients. Consequently, these patients have severe immune system defects and are susceptible to numerous immune system disorders and to opportunistic infections.

The transduced signal through CD40 has different effects, depending on the cell type studied. Generally, ligation of CD40 by T cells expressing the counter-receptor results in activation of the cell. In terms of APCs, this leads to the expression of cytokines that stimulate cells in a paracrine or autocrine manner. CD40 also upregulates cell surface proteins, such as the costimulatory molecules, CD80 and CD86 and other adhesion molecules. Notably, this interplay between costimulatory molecules CD154:CD40 and CD80/86:CD28 forms the basis of reciprocal dialogue between T cells, B cells and other APCs (Figure 1).

For the humoral response to T-dependent antigens, the CD40 signaling pathway apparently complements signals from the BCR that are necessary to promote proliferation. Wheeler and colleagues demonstrated that the signal generated through CD40 effectively lowers the threshold for activation through the BCR. Mice that are genetically deficient for CD40 clearly have abnormal B cell responses to TD antigens, and part of this defect lies in the inability of T cells to stimulate CD40^{-/-} B cells.

Figure 1 Receptor-mediated reciprocal dialog between a T cell and an antigen-presenting cell. Activation of T cells and APCs cause upregulation of costimulatory molecules and their counter-receptors. These molecules enhance the activation process and can lead to proliferation of lymphocytes. Downregulatory molecules such as CD95 and CD152 are important for eliminating lymphocytes after they have served their function. The APC in this figure represents a class of cells, including dendritic cells, macrophages and activated B cells. Not shown in this figure are other surface molecules and secreted compounds which also play an important role in the communication process.

In addition to its costimulatory role, these synergistic signals between CD40 and the BCR may play an integral role in the positive selection of highly antigen-specific B cells during the GC response. As the B cells undergo hypermutation of their antigen receptor, novel specificities are generated. Positive selection of B cells bearing high-affinity receptors is mediated through ligation of the BCR, presumably by interacting with FDC-bound antigen, and ligation of CD40, provided by helper T cells bearing CD154. In studies where *ex vivo* GC B cells are isolated, in the absence of T cell help, these cells eventually undergo programmed cell death. These cells can be rescued via engagement of CD40 with or without BCR ligation. Consistent with this observation is the fact that signaling through CD40 can increase the expression of Bcl-xL, a negative regulator of apoptosis.

CD40 has also been implicated in B cell differentiation. GC B cells which have been positively selected for their high-affinity antigen receptors differentiate by switching of Ig isotype and maturing into long-lasting memory B cells or terminally differentiating into Ig-secreting plasma cells. Cytokines influence the differentiation pathways, especially in the process of isotype switching. There is evidence from *in vitro* systems that demonstrate specific cytokine profiles that result in the development of certain Ig isotypes. The role that CD40 plays in any of the differentiation steps is currently unknown. CD40 activates expression of IL-12 in DCs, which can promote a T_H1 response, yet CD40 can also promote IgE class switch, typical of a T_H2 response.

In addition to the severe defects in humoral immunity, X-linked hyper-IgM syndrome patients appear to have defects in the T cell compartment. They are susceptible to diseases that are typically associated with T cell immunodeficiency. Whether this defect is due to a direct effect from the lack of CD154 signaling on the T cell, or an indirect effect from the lack of CD40-induced activation of the APC, is not clear. There is evidence that CD154 can transduce a signal to T cells. Alternatively, CD154-mediated stimulation of APCs has been shown to be critical in their ability to counterstimulate the T cell.

FasL/CD95 interactions downregulate the immune response

CD95 (Fas, APO-1) is also a member of the TNF-R family. As previously mentioned, TNF-R family members are distinguished by a cysteine-rich extracellular domain. In the cytoplasmic region, some family members contain a 'death domain' which is important for initiating programmed cell death. The death domain mediates binding of the receptor to

intracellular proteins that also contain death domains. These cytoplasmic proteins operating in conjunction with members of a specialized protease family, the caspases, are important in transducing the apoptotic signal.

The expression of CD95 is broadly distributed. It can be detected on the surface of myeloid, stromal and lymphoid cells. High expression of CD95 is observed upon activation of B cells and T cells. Also, experiments with cell lines suggest that expression of CD95 can be upregulated if cells are treated with interferon γ (IFN γ) alone, or in combination with TNF α .

The ligand for CD95, FasL, is a member of the TNF family, and, like the other characterized family members, is a type II membrane protein. FasL can also be secreted, similar to other members such as TNF and LT. The expression of FasL appears to be limited, in contrast to the broader expression pattern of CD95. FasL can be detected on the surface of DCs, activated, mature T lymphocytes and on NK cells. This is consistent with its suspected role in immunoregulatory or killer function. Interestingly, the other tissues which FasL has been detected are small intestine, eye, lung and mouse or rat (but not human) testes. The function of FasL in these tissues is not known but it might protect some tissues, such as eye and testes, from infiltration by activated T cells. Another proposed function for FasL is in T cell deletion by DCs following an immune response. One of the possible sites of activated T cell deletion is believed to be the gut. One particular paradox with the expression of FasL concerns the thymus: FasL expression is not detectable there, despite the fact that thymocytes express high levels of CD95. There is considerable controversy about whether CD95 plays a role in thymocyte selection.

In numerous experimental systems, antibody or soluble FasL ligation of CD95 induces a cell death program. CD95 plays a role in CD8⁺ T cell and NK cell-mediated cytotoxic function. In this context, cytotoxic cells expressing the counter-receptor to CD95 ligate CD95 present on the target cells.

Another interesting role of CD95 is in the regulation of T and B cell maturation. As previously mentioned, activation of mature T or B lymphocytes increases the expression of CD95. This renders the activated cell susceptible to CD95-mediated cell death. Thus, CD95 offers an attractive explanation for how activated lymphocytes are eliminated after they have served their function. For example, during the GC response, CD95 expression is increased on activated B cells which are undergoing the process of somatic hypermutation. CD95 renders them susceptible to FasL-mediated death, unless the B cell is

stimulated effectively through the BCR and CD40. According to this model, anergic B cells may be deleted, as their BCR signaling pathway is inoperative, thereby preventing BCR-mediated rescue from death.

Activated T cells also need to be downregulated, especially following an effective immune response. A possible mechanism by which the expression of CD95 and its counter-receptor on activated, responding T cells could cause apoptosis is by an autocrine or paracrine mechanism. One possibility is that after an effective immune response and the number of target cells becomes limiting, FasL on the surface of the activated killer cell will begin to ligate CD95 on itself or on neighbouring cells. This mechanism is a form of self-limiting effector function.

The importance of CD95-mediated downregulation of the immune response is underscored by the phenotype of mice with naturally occurring *lpr* and *gld* mutations which have genetic disruption of either CD95 or FasL, respectively. The phenotypes are generally similar in either mutant strain: they display an accumulation of lymphocytes in the peripheral lymphoid organs that resembles a lymphoproliferative disorder. While the immune response to antigen is apparently normal, the elimination of the responding cells is impaired in these mice. In the B cell compartment, a defect in the elimination of activated and maturing B cells is reflected by a high production of IgG and IgM antibodies. In *lpr* or *gld* mice that have been bred on to the MRL background (MRL/*lpr* and MRL/*gld* mice), the inability to control autoreactive cells in the periphery is apparent. These mice develop an autoimmune disease resembling that of systemic lupus erythematosus (SLE) in humans. This is marked by the production of autoreactive antibodies such as anti-DNA and rheumatoid factor.

Conclusions

By describing the function of certain IgSF and TNF/TNF-R family of molecules as 'stimulatory' or 'downregulatory', we have presented them in a conventional manner. However, as these molecules become further defined, their function in the process of cellular cooperation must be considered in the context of a cell's activation state and its location. In considering their relevance to the biology of the entire immune response, we have metaphorically compared them to words used by cells to communicate. Depending on the context, these words can effect a different meaning to a message. An example of this is recent evidence suggesting that CD95 may actually have a costimulatory function. Much

remains to be learned, not only about the range of definitions that receptor 'words' may have, but also of the syntax and semantics of this intercellular language.

To conceptualize the cellular communication process, we have described only a small fraction of molecules that are involved. Our intent is to highlight key molecules that function during the discrete steps of the immune response: activation, differentiation and elimination. However, at each step, there are clearly other molecules that have a role in modifying the signals. For example, the CD19/CD21 complex, CD22 and CD45 have been shown to regulate signals through the BCR. At the time of this writing, there are over 160 molecules with a cluster of differentiation (CD) designation. Many of these play important roles in intercellular communication during immune responses. In addition, secreted compounds also play a role in enhancing or modifying cellular fate. Cytokines secreted by APCs and T cells are crucial in determining the type of immune response to a particular antigen. Again, the number of characterized secreted compounds is growing. The challenge that immunologists face is to decipher the multiple signals these molecules provide to a cell during a given maturation step, with the hope of eventually being able to comprehend the intricate language by which cells of the immune system communicate.

COPPER AND THE IMMUNE SYSTEM

Omelan A Lukasewycz, Medical Microbiology and Immunology, Office of Curricular Affairs, School of Medicine, University of Minnesota, Duluth, USA

Human studies

Copper is a trace metal necessary for the development and maintenance of the immune response. The human requirement for copper is approximately 1 mg day^{-1} . Copper is an essential component of many important enzymes, including ceruloplasmin, tyrosinase, lysyl oxidase, cytochrome *c* oxidase, dopamine- β -mono-oxygenase, Cu-Zn superoxide dismutase, and peptidylglycine α -amidating mono-oxygenase.

Copper insufficiency in humans leads to known pathologic states. Menkes' syndrome, an X-linked trait characterized by *pili torti* and cerebral degeneration, is due to a defect in copper metabolism which leads to decreased copper levels in blood, liver and brain. Infants with this defect are extremely susceptible to infection and usually succumb by 2 years of age. Neonatal copper deficiency, though rare, is characterized by a marked neutropenia and is often associated with infections. Children suffering from severe malnutrition do not regain full immunocompetence unless copper supplementation is also included. Recent studies have shown that a low-copper diet in normal adult males causes a significant decrease in the proliferative response of cultured blood leukocytes to mitogen and an increase in the percentage of circulatory B cells.

Animal studies

Impairment of immunity as a consequence of nutritional copper insufficiency is now firmly established in both domestic and laboratory animals. Domestic animals with insufficient copper intake show decreased bactericidal activity, impairment of neutrophil function and a higher susceptibility to a variety of bacterial and fungal infections.

Laboratory models of copper deficiency have been useful in elucidating the potential defects in the immune system. In mice, the effects of copper deficiency are most readily observed in 6-week-old mice that are on a copper-deficient diet from birth. While body weight of animals on deficient diets is equal to copper-supplemented control animals, marked anemia is observed, thymus weights are routinely lower and spleen weights are usually increased.

Electron microscopy of these lymphoid organs shows abnormalities of the nucleus and mitochondria. Ceruloplasmin activity is significantly diminished within a matter of days on the deficient diet and there is a concomitant loss in cytochrome *c* oxidase and Cu-Zn superoxide dismutase activity.

Copper-deficient mice and rats exhibit an alteration in lymphocyte subpopulations, marked by a substantial overall increase in the number of surface immunoglobulin (Ig)-bearing B cells and a relative decrease in the helper T cell subset. Copper deficiency leads to an impairment of the antibody response to sheep erythrocytes and keyhole limpet hemocyanin. Lymphocytes from copper-deficient animals show a decreased response to both B and T cell mitogens. The degree of impairment in antibody production and mitogen responsiveness is proportional to the level of copper deficiency. Copper-deficient mice have a decreased cell-mediated immune response to tumor challenge and impaired natural killer cell activity.

Studies of one-way mixed lymphocyte reactions showed that responder cells from copper-deficient mice had decreased activity to inactivated control cells. Of particular interest was the observation that inactivated copper-deficient cells were poor stimulators for normal responder cells. Since it is now generally accepted that the stimulating antigens in mixed lymphocyte reaction are predominantly the class II histocompatibility antigens, copper deficiency may cause a change in the cell surface density or functional properties of these antigens. The purified lymphocyte plasma membrane from copper-deficient mice is known to have alterations in both protein and lipid content.

Analysis of serum immunoglobulin isotype levels in copper-deficient mice and rats indicate IgG levels to be statistically below control animals and IgM levels to be equivalent.

Cytokine production is altered in copper-deficient mice and rats. Production of interleukin 1 (IL-1) is increased (approximately twofold) relative to copper-supplemented controls, while IL-2 production is substantially lowered (one-third of control values). IL-2 receptor levels and interferon γ production in these copper-deficient animals is equivalent to controls.

Table 1 Cuproenzymes and immunomodulation

<i>Copper enzyme</i>	<i>Function</i>	<i>Immunomodulatory role</i>
Ceruloplasmin	Iron oxidation	Membrane integrity
Cu-Zn Superoxide dismutase	Removes superoxide	Membrane integrity
Cytochrome <i>c</i> oxidase	ATP synthesis	Energy metabolism
Dopamine- β -mono-oxygenase	Norepinephrine synthesis	Affector molecule
Peptidylglycine- α -amidating mono-oxygenase	Vasoactive intestinal peptide synthesis	Affector molecule

Possible mechanisms

Several possible mechanisms may be operative that could explain the pathogenesis of immunologic dysfunction which accompanies copper deficiency (Table 1). These mechanisms may be direct, i.e. the result of flux-limiting changes in specific cuproenzymes, or indirect. The levels of the antioxidant enzymes, Cu-Zn superoxide dismutase and ceruloplasmin, are decreased in copper deficiency and may leave the immunoreactive cells vulnerable to the increased oxygen metabolism known to accompany an activated immune response. It is also conceivable that decreased activity of cytochrome *c* oxidase may limit ATP flux and thus impair lymphocyte and macrophage energy metabolism. The complex interaction between the immune, nervous and reproductive systems may depend on copper. For example, norepinephrine synthesis depends on dopamine- β -mono-oxygenase. Norepinephrine metabolism, known to be altered by copper deficiency, is essential for immune function. Another cuproenzyme, peptidylglycine α -amidating mono-oxygenase, may also be involved; it is responsible for post-translationally modifying a large number of neuroactive peptides, including vasoactive intestinal peptide. Barnea and colleagues have shown that the release of luteinizing hormone-releasing hormone from the median eminence area is greatly amplified in the presence of copper and prostaglandin E_2 . Release of luteinizing hormone from the pituitary has a major effect on

gonadal hormone release, which in turn affects the thymus. The most significant impact of altered copper status may well be the level of production of IL-2.

CORONAVIRUS, INFECTION AND IMMUNITY

Helmut Wege, Institut für Virusdiagnostik, Federal Research Centre for Virus Diseases of Animals, Insel Riems, Germany

The family of Coronaviridae was defined around 1968, primarily by morphologic criteria. The virions are pleomorphic to spherical-shaped particles (120–160 nm diameter), which are surrounded by a fringe of club- or pear-shaped surface projections (12–

24 nm long; **Figure 1**). The virus has a lipid envelope and contains a single-stranded RNA genome of positive polarity. Coronaviruses infect humans, mammals and birds. Based on molecular criteria, the toroviruses represent a second genus within this family.

Figure 1 Coronavirus particle. The HE protein is expressed in a subset of strains only. A small membrane protein, sM, is present in the envelope of TGEV, IBV and MHV (not shown). For explanation, see text.

Furthermore, evolutionary relationships to the Arteriviridae are discussed within the concept of a 'coronavirus-like' superfamily.

Structure and replication of coronaviruses

Coronaviruses replicate in the cytoplasm and mature by budding through the Golgi apparatus and the rough endoplasmic reticulum. Their genome – a large, single-stranded molecule (size 27 000–31 500 nucleotides) – has the properties of a mRNA, namely a 5' cap structure and a polyadenylated 3' end. The replicase or polymerase gene 'Pol' is located at the 5' end and contains two large open reading frames (ORF 1a and 1b, about 20 000 nucleotides) which are expressed as a fusion protein involving ribosomal frame shifting. The polymerase products generate RNA templates for replication of genomic and subgenomic mRNAs. These mRNAs contain a common 5' leader sequence (65–100 nucleotides) that is derived from the 3' end of the negative-sense template and is essential for a discontinuous transcription mechanism. The viral proteins are translated from a nested set of 5–7 overlapping subgenomic mRNAs with common 3' ends. In general, only the 5' end of each mRNA is translated into a single viral polypeptide. Certain mRNAs for nonstructural viral proteins can employ up to three ORFs via internal initiation.

All coronaviruses contain a large surface protein (S, spike, about 200 kDa), a matrix protein M (20–30 kDa) and a nucleocapsid protein N (50–60 kDa).

Bovine coronavirus (BCV), human coronavirus (HCV)-OC43, hemagglutinating encephalomyelitis virus (HEV), turkey coronavirus (TCV) and some mouse hepatitis virus (MHV) strains express a hemagglutinin esterase glycoprotein termed HE (65 kDa). A small membrane protein sM (9.1–12.4 kDa) was demonstrated for transmissible gastroenteritis virus (TGEV), infectious bronchitis virus (IBV) and MHV. The typical gene order for coronaviruses is Pol-S-M-N. The position and expression of genes for HE, sM and nonstructural proteins varies between strains in a complex pattern. The helical nucleocapsid contains the genome and is surrounded by a lipid envelope (Figure 1). The M glycoprotein (20–30 kDa) spans this envelope three times. Peplomers (large bulbous projections) are formed by the glycoprotein S, which is cleaved in many coronaviruses to subunits of about 90 kDa (S1 and S2). The S protein induces cell fusion and binds to the host-cell receptor. A smaller fringe of spikes is formed by the HE protein, which promotes binding by interaction with 9-O-acetylated neuraminic acid.

Antigenic relationships

The majority of coronaviruses fall into three serologically distinct clusters (Table 1). Within each cluster, different antigenic relationships exist. The evolutionary relationships indicated by sequence data correlate by and large with this classification. Human and porcine coronaviruses are distributed in two clusters. The large number of serotypes for some coronaviruses (e.g. HCV, IBV and MHV) may result from recombination and high mutation frequencies. The S protein in particular displays a strong polymorphism. Enteric coronaviruses comprise only one serotype per group.

Diseases caused by coronaviruses

A variety of diseases of clinical and economic importance are caused by coronaviruses (Table 1). The majority of diseases are associated with infections of the respiratory and gastrointestinal tract. Most infections lead to acute and self-limiting diseases. Human coronaviruses are responsible for up to 30% of upper respiratory diseases, which display some periodicity in winter and spring. These viruses are difficult to isolate in tissue or organ cultures. The association of coronavirus-like particles with non-bacterial gastroenteritis is not clear.

Of veterinary importance are avian IBV, BCV, several porcine strains (e.g. TGEV, HEV and porcine respiratory coronavirus (PRCV)) and feline infectious peritonitis viruses (FIPV). Enteric coronaviruses

Table 1 Coronavirus-induced diseases

<i>Antigenic cluster</i>	<i>Virus family</i>	<i>Designation</i>	<i>Natural host</i>	<i>Typical diseases</i>
I	Canine coronavirus	CCV	Dog	Enteritis
	Feline enteric coronavirus	FECV	Cat	Enteritis
	Feline infectious peritonitis virus	FIPV	Cat	Peritonitis, granulomas
	Human coronavirus (229E)	HCV	Human	Respiratory disease
	Porcine epidemic diarrhea virus	PEDV	Pig	Respiratory disease
	Porcine respiratory coronavirus	PRCV	Pig	Respiratory disease
	Rabbit coronavirus	RbCV	Rabbit	Cardiomyopathy, enteritis
	Transmissible gastroenteritis virus	TGEV	Pig	Enteritis
II	Bovine coronavirus	BCV	Cow	Enteritis
	Human coronavirus (OC43)	HCV	Human	Respiratory disease
	Hemagglutinating encephalomyelitis virus	HEV	Pig	Vomiting and wasting, encephalomyelitis
	Mouse hepatitis virus	MHV	Mouse	Hepatitis, encephalomyelitis, enteritis, vasculitis
	Rat coronavirus	RCV	Rat	Respiratory disease
	Turkey coronavirus	TCV	Turkey	Enteritis
	Infectious bronchitis virus	IBV	Chicken	Respiratory disease, nephritis, gonaditis

are only of limited pathogenicity for older animals; respiratory viruses affect adults as well. Some strains are neurotropic, others can involve many different organs. Several coronaviruses readily establish chronic infections, which can remain inapparent or modulate immune responses. In this context, MHV infections of small rodents are interesting models for investigating pathogenetic mechanisms such as demyelination or immunosuppression. Furthermore, FIPV infections in particular induce a variety of antibody-mediated immunopathologic mechanisms.

Immune responses to coronaviruses

Antibodies are generated against all structural proteins. The peplomer protein S is the major antigen for induction of neutralizing and fusion-inhibiting antibodies. Furthermore, antibodies specific for HE, N, M and sM have also been implicated in neutralization, especially in association with complement factors. Important antigenic sites of major coronavirus families are in general well defined. The bulbous S1 subunit of IBV displays high antigenic variability and induces serotype-specific neutralizing antibodies which bind to discontinuous epitopes. More conserved sites forming linear epitopes are present on the S2 subunit (stalk) and an immunodominant region was identified which is recognized by antisera against different strains. The most immunogenic sites of BCV and MHV are concentrated on the S1 subunit of the molecule. The S2 subunit of MHV also induces neutralizing and fusion-inhibiting antibodies. The neutralization of TGEV involves four major

antigenic sites in the S protein, which help to differentiate members of this cluster.

BCV-specific antibodies against the HE protein are involved in neutralization. Furthermore, the M protein of MHV and TGEV induces complement-dependent neutralizing antibodies. The sM protein of TGEV appears also to be involved in neutralization. T cell responses against defined sites in the S and N protein contribute to virus elimination and can confer protection against encephalomyelitis in mice and rats. An immunodominant T cell antigenic site in the N protein of MHV helps to elicit neutralizing S protein-specific antibodies. Such T cell epitopes within the N protein have also been defined for TGEV and IBV.

Epidemiology and prevention

Coronaviruses are distributed throughout the world. Transmission does not involve vectors other than the host and occurs mostly by the oral-fecal route. The frequency of reinfection by human coronaviruses is high and vaccination may be indicated only in special cases. Administration of recombinant interferon α to volunteers prevented disease when treatment was started before infection. Mucosal immunity plays a pivotal role for the defense against respiratory and enteric coronavirus infections. The serum antibody profile does not correlate well with protection.

Licensed vaccines with attenuated live viruses exist for BCV, FIPV, IBV and TGEV. Protection against IBV is most efficient if the virus is administered to the trachea, but the continuous emergence of antigenic

variants prevents effective vaccination. Recombinant vaccinia viruses which express the S protein of IBV or FIPV can induce specific immunity; however, protection experiments with FIPV failed because antibodies elicited by defined antigenic sites of S protein accelerate the disease (antibody-mediated enhancement). Attempts to vaccinate cats with related coronaviruses were also without success.

In the mouse model, protection against encephalitis can be achieved by vaccination with a peptide which represents a surface domain of the S protein. Furthermore, immune responses against other viral proteins contribute to protection. For example, BCoV can be neutralized *in vivo* by monoclonal antibodies against HE protein, and adenovirus recombinants expressing HE are capable of inducing both systemic and mucosal HE-specific immunity in cotton rats.

Enteric coronavirus infections of piglets under the age of 10 days cause high mortality that cannot be prevented by vaccination of sows. Suckling animals are naturally protected by maternal antibodies contained in milk and colostrum. This protection is mediated mainly by neutralizing S-specific IgA antibodies. Protection against TGEV can also be achieved by administration of specific serum or monoclonal antibodies. Immunization of pregnant animals with attenuated live virus is a feasible approach to control the spread of virus.

Newer experimental vaccines are mainly based on three approaches: noninfectious antigens which can be targeted to the mucosa; live vectors with enteric tropism; or internal image anti-idiotypic antibodies

which mimic protective epitopes on the virus. Examples for these strategies are antigenic constructs based on peptides which represent viral immunodominant sites combined with T cell factors or bacterial components which selectively induce mucosal immunity. Furthermore, vaccines employing live bacterial vectors, adenoviruses, porcine poxviruses or genetically engineered coronaviruses are under investigation.

CORYNEFORM BACTERIA, INFECTION AND IMMUNITY

WC Noble, Department of Microbial Diseases, The Institute of Dermatology, United Medical and Dental Schools of Guy's and St Thomas' Hospital, St Thomas' Hospital, London, UK

Coryneform bacteria from mammalian sources can be assigned to five genera: *Brevibacterium*, *Corynebacterium*, *Dermabacter*, *Propionibacterium* and *Rhodococcus*. All are gram-positive, nonspore-forming bacilli, distinguished chiefly on their cell wall composition; speciation within the genera is incomplete.

Brevibacterium spp. are aerobic, nonlipid-requiring organisms which are sometimes referred to as 'large colony coryneforms'. Their pathogenic role is uncertain except in forms of tinea pedis associated

with malodor caused by proteolytic destruction of the skin. Bloodstream infections are reported on rare occasions.

Corynebacterium spp. include many of the best speciated organisms; they frequently need lipid for adequate growth *in vitro* and are often microaerophils; they may be called the 'small colony coryneforms'. The localized skin disease erythrasma is caused by an overgrowth of the normal skin inhabitant *C. minutissimum*, whilst a variety of normal axillary inhabitants are associated with pronounced

axillary odor which results from microbial modifications of apocrine steroid secretions.

Corynebacterium diphtheriae, the best studied and most serious pathogen, gives rise to toxinogenic pharyngeal diphtheria and also to less severe skin infections. Toxin production occurs following lysogenization of *C. diphtheriae* by tox⁺ phages, several of which have been described though most have similar DNA structures. Tox⁺ phages are also able to lysogenize *C. pseudotuberculosis* (*C. ovis*) and *C. ulcerans*, causing these organisms to produce diphtheria toxin. The toxin is a 535 amino acid polypeptide of 58.3 kDa. When nicked by trypsin at specific sites, it forms two dissimilar fragments which remain joined to form an enzymically active molecule catalyzing ADP ribosylation of elongation factor 2 (EF2) with nicotinamide adenine dinucleotide as substrate. EF2 is an enzyme present in the cytoplasm of eukaryotic cells and is essential for peptide synthesis. Ribosylation of this enzyme inhibits protein synthesis and results in the necrotic lesions of diphtheria. A single molecule of the A fraction of toxin, which contains the ribosylating activity, is lethal to a cell within hours if introduced into the cytoplasm but neither A nor B fragment is toxic extracellularly. Since the toxins produced by all strains of *C. diphtheriae* are immunologically identical, immunity is achieved by immunizing with a single toxoid; there is no type-specific immunity. The immunized individual is not protected against infection but against the systemic and local necrotic effects of the toxin; the degree of immunity conferred is high but not complete.

Caseous lymphadenitis in sheep and goats and ulcerative lymphangitis in horses results from infection with *C. pseudotuberculosis*. The disease is pyogenic despite the fact that *C. pseudotuberculosis* may produce its own toxin ('*C. ovis* toxin') as well as diphtheria toxin. The toxins appear to play little part in animal disease. *C. ulcerans* is also able to produce both these toxins and has given rise to classical diphtheria in humans. The *C. renale*, *C. pilosum*, *C. cystitidis* group cause bovine cystitis and pyelonephritis associated with extensive necrosis.

Corynebacterium jeikeium is most frequently characterized by resistance to most common antibiotics. Although found on normal human skin it causes low-grade bacteremias, generally in the immunosuppressed and particularly in males with leukemia. The mechanism of pathogenesis is unknown. *C. urealyticum* is similarly a skin resident and resistant to many antibiotics, it is a rare cause of kidney stones.

Dermabacter hominis is a recently described large colony coryneform from human skin which is re-

cognized as a rare cause of bacteremia and deep infection.

Propionibacterium spp. require lipid and anaerobic conditions for successful cultivation *in vitro*. *P. acnes* and *P. granulosum* are isolated from highly sebaceous areas of human skin in all those past puberty; *P. avidum* is similarly found in the axilla. The first two species are associated with acne and are occasionally recovered from deep infections in humans. There is no consensus on the role of propionibacteria in acne. Not all acne lesions contain microorganisms but a potential role for propionibacteria may be as follows: they reside in the ducts of sebaceous glands which become blocked as a result of changes in keratinization; sebum continues to be produced so that the blocked duct forms a closed comedo. *In vitro*, *P. acnes* has sharp pH and pO₂ optima for the production of hyaluronidase and protease; production of these enzymes *in vivo*, if it occurs, would render the comedo wall leaky to host-defense mechanisms; triggering of the alternative complement pathway by the cell wall of *P. acnes* or by protease would account for erythema and the recruitment of white cells to form a pustule. The serological picture is complicated by the almost universal existence of antibody to *P. acnes*. There is switch from predominantly immunoglobulin M (IgM) in children to IgG in adults. Antibodies to hyaluronidase are found in only about 10% of adults and this may indicate that exocellular enzymes have little role in acne. Cellular immunity in acne is a late event which probably does not contribute to lesion formation. The immunostimulator '*Corynebacterium parvum*' is a mixture of propionibacteria similar to that found on the skin.

Propionibacterium propionicus (*Arachnia propionica*) is a normal inhabitant of the human oral cavity which causes lachrymal duct infections.

Rhodococcus spp. may be difficult to distinguish from *Corynebacterium* spp. unless red pigmented colonies are seen or details of mycolic acid structure obtained, since the two grow under similar conditions *in vitro*. *R. equi*, a facultative intracellular organism, produces a potentially fatal suppurative bronchopneumonia in foals with intense inflammation of the lymph nodes. *Rhodococcus* spp. are rare pathogens of humans, occurring most frequently in the severely immunosuppressed.

C-REACTIVE PROTEIN

Mark B Pepys, Immunological Medicine Unit, Department of Medicine, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK

C-reactive protein (CRP) is a member of the pentraxin family of plasma proteins, which are unrelated to other known proteins but which are themselves stably conserved in vertebrate evolution. There is even a homologous CRP-like protein which is a major constituent of the blood of the so-called horseshoe crab, the arachnid *Limulus polyphemus*. The other pentraxin in humans is serum amyloid P component (SAP), which shares 55% identity of amino acid sequence with CRP. CRP is composed of five identical nonglycosylated 206 amino acid polypeptide subunits, each of M_r 23027 Da, which are noncovalently associated in a disc with cyclic pentameric symmetry. The crystal structure of CRP is very similar to that of SAP and shares with it the characteristic tertiary fold that identifies these proteins as members of the 'lectin fold' superfamily, which includes concanavalin A, pea lectin, and a variety of human, animal, plant and bacterial carbohydrate-binding proteins. There is a single functional copy of the human gene for CRP, located on chromosome 1, and no polymorphism of either the coding sequence or of the protein itself has yet been described, nor has any individual lacking CRP been identified. CRP is secreted only by hepatocytes and its production is regulated by cytokines, particularly interleukin 6 (IL-6). In regions flanking the CRP gene IL6-responsive promoter elements, and hepatocyte-specific nuclear proteins which interact with them, have been identified in studies of human CRP gene expression in transgenic mice and in human hepatoma cells.

In normal healthy subjects CRP is a trace plasma protein, median level 0.8 mg L^{-1} , with 90% of individuals having levels less than 3 mg L^{-1} and 99% less than 10 mg L^{-1} . In response to bacterial infection, trauma, necrosis of tissue, and most forms of inflammation and malignant neoplasia, CRP production is rapidly and dramatically increased and

serum levels can exceed 300 mg L^{-1} by 48 hours after an acute event. In chronic infections and inflammatory disorders CRP levels may be persistently high, but with resolution or remission of pathology, either spontaneously or in response to treatment, the CRP concentration falls rapidly to normal. Although there is a range of variation in CRP levels for a given apparent state of disease activity in groups of patients with any particular condition, the CRP values in individual patients closely reflect the extent and activity of their disease.

Severe viral infections are usually associated with a significant acute phase response but localized viral infections are generally a much less potent stimulus for CRP production than bacterial infections. In addition there are some important disorders in which CRP levels are usually normal or only modestly increased, even in the presence of severe, active, tissue-damaging pathology. These include systemic lupus erythematosus (SLE), ulcerative colitis, dermatomyositis, scleroderma, Sjögren's syndrome and leukemia. However, in all of them, intercurrent microbial, and especially bacterial, infection always stimulates a major acute phase response. The mechanisms underlying these phenomena are not known. Studies of SLE-like autoimmune disease in inbred mouse strains suggest that the acute phase response to this type of autologous tissue damage may be genetically determined, but the locus of gene action, whether at the level of mediators, receptors, acute phase protein synthesis or catabolism has not been established.

Despite ignorance of the underlying pathophysiological processes, the enormous accumulated experience of clinical CRP measurement underlies its very widespread and rapidly increasing use in routine medical practice. It is the single most sensitive non-specific screening test for organic disease, it is

exceptionally valuable as an objective marker of disease activity, and it is a unique and sensitive test for intercurrent microbial infection, especially in immunocompromised and other at-risk patients. The recent discovery that low grade CRP responses, demonstrable only with high sensitivity immunoassays, are of prognostic significance in coronary heart disease has opened a whole new field of research and practical application.

For clinical purposes it is particularly important that the rapid turnover of CRP (plasma half-life 19 hours) is constant and unaffected by intercurrent pathology. The only significant determinant of the plasma level is the synthesis rate, which generally reflects closely the extent and activity of the disorder stimulating the acute phase response. Furthermore, except in severe hepatocellular insufficiency, CRP production *per se* is impaired neither by disease nor by any treatment, unless that treatment affects the underlying disease activity. Thus CRP measurements are greatly superior to the use of erythrocyte sedimentation rate (ESR), which when used as a marker of the acute phase response is imprecise, variable, insensitive and slow to respond to changes in disease activity or effects of treatment.

CRP was discovered and named because of its interaction with the somatic C-polysaccharide of pneumococci, a ribitol teichoic acid containing phosphocholine. In the presence of calcium, CRP binds specifically and with greatest affinity to phosphocholine. It also reacts with phosphoethanolamine, and less avidly with some galactans, zwitterions and polyanions. In the absence of calcium, that is under nonphysiological conditions, it can also bind to polycations such as histones and protamine. Avid binding of CRP to chromatin has been observed at low ionic strength but does not occur under physiological conditions, in contrast to SAP which is the physiological chromatin and DNA-binding protein of the plasma. CRP does, however, bind specifically and selectively to small nuclear ribonucleoprotein particles (snRNPs).

Although CRP binds to phosphocholine with much greater affinity than to all its other known ligands, and such binding is very likely to be of functional significance, CRP does not interact indiscriminately with any phosphocholine-containing molecule. There is no interaction, for example, with the plasma membrane phospholipids of normal healthy cells or with plasma high density lipoprotein particles. On the other hand CRP does bind strongly to platelet-activating factor (PAF), the potent inflammatory mediator, and aggregated CRP selectively binds low density and very low-density lipoprotein from whole plasma.

Having bound to its ligands CRP produces a number of secondary effects which resemble those of antibodies and include neutralization of biological activity (in the case of PAF), precipitation of soluble ligands, agglutination of particulate ligands and activation of the classical complement pathway. CRP in some circumstances can act as an opsonin, particularly as a result of complement activation, although the existence and importance of receptors on phagocytic cells for bound CRP is not entirely clear. Human CRP passively administered to mice confers dramatic protection against pneumococcal infection, and CRP may be a factor in host resistance to this or other infections in autologous systems. There is evidence that in particular circumstances CRP may have proinflammatory activity, but there is little to suggest that this is a general phenomenon. On the contrary, CRP can inhibit chemotaxis and accumulation of neutrophils in *in vivo* models of lung inflammation. CRP stimulates production of tissue factor by mononuclear phagocytes and may therefore have effects on coagulation.

A very large number of other biological properties have been ascribed to CRP in a variety of different experimental systems *in vitro* and *in vivo*, involving platelets, phagocytic cells and lymphocytes, inflammation, infection and neoplasia. Many of these reports have not been reproducible and others are unlikely to be of physiological relevance. As a result, the function(s) of CRP in health and disease are still unknown. They may well be multiple, and include modulation of inflammation, participation in handling of damaged or dead cells and involvement in lipid metabolism.

CRYOGLOBULIN

John T Whicher, School of Medicine, University of Leeds, Leeds, UK

The first case of cryoglobulin was described in 1933 by Wintrobe and Buell in a patient with multiple myeloma complicated by hepatosplenomegaly, Raynaud phenomenon, purpura and retinal thrombosis, whose serum formed a precipitate when cooled. It was, however, Lerner and Watson in 1947 who, having characterized the precipitate in a patient suffering from 'allergic purpura' as immunoglobulin, coined the term cryoglobulin.

Cryoglobulins are now defined as immunoglobulins which precipitate or form a gel below 37°C (Figure 1). This is usually reversible on rewarming. At low concentrations they precipitate only around 4°C but, in general, the higher the concentration the higher the temperature of precipitation. Small amounts of cryoglobulin of about 30 mg l⁻¹ occur normally in human serum, while symptoms may be associated with concentrations above 100 mg l⁻¹. Concentrations of several grams per liter may, however, occur in the absence of symptoms.

Classification

Immunochemical analysis of purified cryoglobulins allows their classification into three groups. Different studies show rather discrepant figures for the incidence of the various types; those from a recent large study are used here (Monti *et al*, 1995).

Type I cryoglobulins, made of isolated monoclonal immunoglobulins, are found almost exclusively (90% of cases) in patients with malignant B cell tumors. They account for 5–10% of cryoglobulinemias. Most often the monoclonal immunoglobulin is

Figure 1 Serum from a patient with type I cryoglobulinemia as seen after standing at 4°C (courtesy of Professor JR Hobbs). (Reproduced with permission from Whicher JT (1994) *Plasma Proteins*. In: Williams DL and Marks V (eds) *Scientific Foundations of Biochemistry in Clinical Practice*, 2nd edn. Oxford: Butterworth-Heinemann.)

IgM, less often IgG (usually IgG2 or IgG3), occasionally IgA and very rarely Bence Jones protein.

Type II cryoglobulins are mixed cryoglobulins with a monoclonal component possessing antibody activity towards polyclonal IgG. They account for about 50–65% of cryoglobulinemias. The monoclonal component is most commonly IgM κ and possesses 'rheumatoid factor' activity and frequently anti-idiotypic activity. Occasionally it might be IgG or IgA in type. Such cryoglobulins are most often idiopathic and (along with some type III) are referred to as 'essential mixed cryoglobulinemias' though some may be associated with immune responses to infectious agents or with chronic inflammatory disorders. About 40% of type II cryoglobulins are secondary to B cell tumors and such a pathology must be rigorously excluded before labeling a case as 'essential'.

Type III cryoglobulins are mixed cryoglobulins composed of one or more classes of polyclonal immunoglobulins, most commonly IgM, in the form of immunoglobulin–anti-immunoglobulin complexes. Nonimmunoglobulin molecules such as complement components and lipoproteins may be included in the complex: fibronectin is invariably present. They account for about 30–40% of cryoglobulinemias. About half of these cases are associated with either active antibody responses to infectious agents (e.g. streptococcal antigens) or cirrhosis and certain connective tissue diseases (notably Sjögren syndrome, systemic lupus erythematosus and progressive systemic sclerosis).

Essential mixed cryoglobulinemia is frequently associated with chronic hepatitis. Studies suggest that the majority of these patients show hepatitis C virus (HCV) RNA sequences in the serum. About 50% have antibodies to HCV and also suffer from more cryoglobulin-associated symptoms.

Clinical manifestations

The classical symptoms of cryoglobulinemia arise in the type II and type III forms when the mixed cryoglobulin activates and binds complement, resulting in immune complex vasculitis. In both types 90% of cases show evidence of complement consumption (decreased CH50 C3 or C4 in the serum) and the vasculitic lesions invariably contain bound complement. The commonest features are shown in Table 1. Purpura is intermittent, nonitchy and associated with cooling of exposed parts of the lower extremities. Chronic leg ulcers may be associated with purpura. Arthralgia is intermittent, symmetrical and nonmigrating. Renal damage may be progressive with proteinuria, hypertension and renal failure.

Table 1 Clinical features of mixed cryoglobulinemia

Signs and symptoms	Approximate %
Purpura	90
Hepatomegaly	70
Splenomegaly	50
Arthralgia	60
Weakness	60
Raynaud phenomenon	40
Leg ulcers	30
Proteinuria	50
Renal failure	40
Abnormal liver function tests	30

Renal biopsies show proliferative or membranoproliferative glomerulonephritis.

In type I cryoglobulinemia symptoms are less marked, with purpura, arthralgia and renal involvement often being absent. When they do occur they result primarily from increasing viscosity in the peripheral capillaries causing Raynaud's phenomenon, extensive gangrene and recurrent distal necrosis (Figure 2). Occasional arterial thrombosis may occur. *In vitro* cryoprecipitation can be demonstrated quite clearly in many sera containing monoclonal immunoglobulins, particularly after storage for several days at 4°C, with no obvious clinical sequelae.

Laboratory investigations

The laboratory investigation of cryoglobulinemia is aimed at detecting cryoglobulins in patients with suggestive symptoms and characterizing them according to type. It is important to appreciate that

Figure 2 Digital gangrene in a patient with cryoglobulinemia (Kindly supplied by Dr P Copeman.) (Reproduced with permission from Whicher JT (1994) *Plasma Proteins*. Figure 3 The laboratory investigation of cryoglobulin.

in the absence of obvious underlying disease, the diagnosis of 'essential cryoglobulinemia' must be kept under continuous review as it is very likely to represent 1) the preclinical stage of a lymphoproliferative disease; 2) the only sign of an underlying infection or chronic inflammatory disease; 3) the preclinical stage of cirrhosis or chronic active hepatitis.

To detect cryoglobulins, blood samples should be sent to the laboratory warm and separated at 37°C. The investigative procedure is summarized in **Figure 3**. The precipitate does not always redissolve easily, probably due to intermolecular disulfide bond formation. Electrophoresis of the warmed serum and the redissolved precipitate reveals a monoclonal component in about 60% of cases (type I or type II). In type II cases this is most often IgM κ but confusion may arise as the monoclonal band seen on electrophoresis may be found to contain IgM, IgG, κ and λ on immunofixation or immunoelectrophoresis owing to the presence of bound polyclonal IgG.

The analysis of cryoprecipitates in trace amounts

using two-dimensional polyacrylamide gel electrophoresis, has shown that polyclonal IgG are associated with a mixture of polyclonal and monoclonal IgM. These cryoglobulins have been tentatively named type II–III cryoglobulins. They are theoretically relevant since they may represent the transition from type III (mixed-polyclonal) to type II (mixed-monoclonal) cryoglobulins. This transformation could be induced by the chronic antigen stimulation caused by persistent HCV infection documented in most patients with 'essential' mixed cryoglobulinemia.

Patients with cryoglobulins containing a monoclonal component should be investigated for an underlying lymphoproliferative disease and the presence of hypogammaglobulinemia and/or Bence Jones proteins are useful indicators.

Mixed cryoglobulins frequently have anticomplementary activity and low serum complement levels, especially of C4, may be seen.

Immunohistological studies of skin lesions in cryoglobulinemia show IgM, IgG and/or C4 in the blood vessel walls.

CRYOPRESERVATION OF IMMUNE CELLS

Patrick J. Stiff, Loyola University Medical Center, Maywood, Illinois, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Primitive experiments in cryopreservation date to the mid-eighteenth century but it was not until 1949 that Polge first used glycerol to successfully cryopreserve both animal and human spermatozoa at -79°C . After the demonstration of glycerol's effect on the low-temperature storage of spermatozoa, early cryopreservation studies focused on the use of glycerol and then dimethylsulfoxide (DMSO) to cryopreserve murine bone marrow for syngeneic bone marrow transplantation. The goal was to circumvent the lethal effects of radiation on the bone marrow, which were first seen as a result of the atomic bombs that had been dropped on Japan a few years earlier. These initial studies demonstrated the efficacy of these agents in the cryopreservation of marrow cells frozen at a constant rate of $1^{\circ}\text{C min}^{-1}$ to -79°C , with storage for periods up to 6 months. Viability was determined by the demonstration of viable cells post-thaw by dye exclusion studies and the successful engraftment of the bone marrow when injected into syngeneic animals after lethal irradiation. This technology now forms the basis of numerous successful autologous bone marrow transplant programs worldwide, with clinical successes not only in the leukemias and lymphomas but also in solid tumors.

The use of cryopreserved lymphocytes for *in vitro* studies is also now commonplace. The initial studies were reported in 1964 by Ashwood-Smith, who cryopreserved murine lymphocytes using 15% DMSO. Cells were held in liquid nitrogen (-196°C) for 3 months and then assayed for viability, both by using phase microscopy and by the demonstration of splenomegaly after they were injected into irradiated hybrid mice. With the need for standardization of cytochemical staining, surface marker analysis and *in vitro* stimulation studies of lymphocytes, cryopreservation subsequently became the easy way to store cells for comparative studies. It is now easy to follow and compare changes over time or after therapy in individual patients using cryopreserved cells, with all assays done at the same time. While cryopreservation is used mainly for *in vitro* testing of lymphocytes, with the advent of recombinant cytokine therapy, cryopreservation may permit the storage of large numbers of either resting or 'stimulated' lymphocytes treated *ex vivo*, either after or before cryopreservation, in an attempt to augment the *in vivo* immune response to tumor cells. When infused later at a time of minimal residual disease, they might decrease

relapses when used as consolidation therapy following conventional or transplant therapies.

Cryoprotectants and the freezing process

The initial use of glycerol for the freezing of spermatozoa was a 'chance observation' in 1949; it and other cryoprotectants work by stabilizing cell membranes and intracellular contents during the freezing and thawing processes. Glycerol and related compounds and DMSO are intracellular cryoprotectants in that they diffuse readily into the cell when added prior to cryopreservation, while hydroxyethyl starch (HES), dextran and polyvinylpyrrolidone (PVP) act as extracellular cryoprotectants by stabilizing the cell membrane during the freezing and thawing process. Lethal damage to cells can occur at various points in the freezing-thawing process, with the majority of damage occurring during the phase change from liquid to solid, and during the thawing and manipulation of the previously frozen cells. When cells in suspension are cooled, extracellular ice crystals form, raising the intracellular solute concentration. This osmotic change, if it occurs in the absence of a cryoprotectant, can lead to their death with cell membrane lysis. While rapid cooling decreases water shifts, it causes cell death due to intracellular ice formation. By diffusing into the cell, intracellular cryoprotectants decrease the solute shifts that occur during the freeze-thaw cycle, thereby decreasing the potential damage caused by high intracellular solute concentrations. This permits the use of slow cooling rates ($1-3^{\circ}\text{C min}^{-1}$), which in turn decreases the risk of damage caused by intracellular ice formation when faster rates are used.

The phase change from liquid to solid, with the liberation of the heat of fusion that occurs during the freezing process, can also be damaging to the cells. Without the use of a controlled-rate freezing apparatus, the temperature can actually rise several degrees (heat of fusion), and does not begin to fall again until the entire solution has been frozen. A rapid transit during this transition at $1^{\circ}\text{C min}^{-1}$ appears to be optimal for the preservation of marrow stem cells, but seems to be less critical for other cells, including lymphocytes and platelets, especially when small aliquots with a greater surface area available for the dispersion of this heat are available.

While little damage is felt to occur during storage

at low temperatures, provided that there are no significant temperature fluctuations, significant damage can occur during the thawing of the cryopreserved cells. During the thawing process, cells swell because of the reversal of the water shifts that occur during freezing. Intracellular cryoprotectants that diffuse out of the cells rapidly, extracellular cryoprotectants and proteins, including albumin, appear to decrease the damage to cell membranes that occurs during this swelling. While some controversy exists as to the best way to thaw frozen cells, in general most cells thaw rapidly and, once thawed, should be diluted slowly, 1:1 over 3–10 min, and then more rapidly to minimize further swelling. When used for transplantation purposes the thawed cells are infused rapidly, unfiltered and undiluted.

While effective at low temperatures, intracellular cryoprotectants such as DMSO are toxic to cells at room temperatures or higher. For optimal use, DMSO should be added at 4°C just prior to freezing. In addition, for *in vitro* work it should be diluted or washed to a concentration of <1% as soon as possible post thaw. A recent analysis of the mechanism of action of DMSO by Arakawa suggests a reason for the disparity of the effects of DMSO at different temperatures. At low temperatures, DMSO is excluded from the hydration cover of proteins which leads to their stabilization during the freezing process; however, at room temperatures DMSO interacts in a hydrophobic way with these same proteins, leading to denaturation or destabilization. Exposure at concentrations >1% for as little as 30–60 min is sufficient to cause irreversible cell membrane damage.

Cryopreservation techniques

Hematopoietic stem cells

There are currently two methods of hematopoietic stem cell cryopreservation in use worldwide. The most commonly employed method is based on the animal studies of the 1950s. After bone marrow is harvested in the operating room, it is brought to the cryopreservation laboratory where, using a cell sorter or density gradient separation, the majority of the red cells are removed. After adjusting the cell count to 60–70 million ml⁻¹, using tissue culture media admixed with 20% autologous plasma, an equal volume of media/plasma solution containing 20% DMSO is slowly admixed with the cells at 4°C; 100 ml aliquots are then placed into polyolefin freezing bags, sealed, placed into aluminum freezing frames and then frozen using a programmable rate-controlled freezer, at a constant freezing rate of

1°C min⁻¹ to –80–120°C, at which time the bags are placed into the liquid or vapor phase of liquid nitrogen. At the time of reinfusion, the cells are thawed at the bedside and infused rapidly over 5–15 min. Rapid reinfusion is required because this method does not successfully cryopreserve granulocytes, which lyse rapidly after thawing and release nucleoproteins which cause clumping and a gel formation if left at room temperature for even 30 min.

A newer method, which has also been proven to be effective for both marrow and blood stem cells, uses a combination of both DMSO, an intracellular cryoprotectant, and low molecular weight HES, an extracellular cryoprotectant. This combination successfully cryopreserves both stem cells and terminally differentiated granulocytes, permitting the cryopreservation of large volumes of bone marrow in a single bag. In addition, this method does not require the use of a rate-controlled freezing process, nor does it require storage at liquid nitrogen temperatures (although recent data suggest that cells preserved in DMSO alone can also be frozen without a rate-controlled freezer or stored for short periods at –80°C). After harvesting, the majority of the red cells are removed as described above. The cells are brought to a final volume of 300 ml and are admixed with an equal volume of a cryoprotectant solution containing 10% DMSO, 12% HES and 8% human albumin in lieu of autologous plasma; 300 ml aliquots are placed into freezing bags, which are then placed into aluminum freezing frames. The marrow is frozen and stored simply by placement in a –80°C freezer, where it is kept until it is autotransfused. Reinfusion is done by infusing the 300 ml aliquots over 30 min each. Successful engraftment has been seen for cells stored at –80°C for periods of 2 years.

The newest source of stem cells being utilized for transplantation is cord blood, obtained at birth and used primarily for unrelated allogeneic transplantation. Cord blood banks are being developed in many countries, using standard cryopreservation techniques; successfully thawed, these cells are used as a transplant source primarily for children who have neither a related sibling donor nor an unrelated donor available through national and international computer registries. While standard cryopreservation techniques are used, many programs concentrate the stem cells (HES sedimentation) prior to cryopreservation to maximize freezer space. This type of transplant will likely increase as there appears to be a lower incidence of graft versus host disease. Furthermore, techniques have been developed to expand hematopoietic stem cells *ex vivo*, making these grafts available to adults.

Lymphocytes

While post-thaw recovery of cryopreserved lymphocytes appears to be optimal when the cells are frozen in 7.5–10% DMSO using a rate-controlled freezing process at $1^{\circ}\text{C min}^{-1}$, many routinely freeze lymphocytes by simple placement into a -80°C freezer, or even by simple placement in insulated containers into the vapor phase of liquid nitrogen. Alternatively, lymphocytes can be held at room temperature for several days if nutrient media are properly buffered at pH 7.0 with HEPES buffer, and care is taken to avoid bacterial contamination. The cryopreservation process using rate-controlled freezing is similar to that for bone marrow; however, after freezing to -30°C at $1^{\circ}\text{C min}^{-1}$ the rate is increased to $5^{\circ}\text{C min}^{-1}$ to -80°C , at which time the cells are transferred to the vapor phase of liquid nitrogen. Alternatively, good results can be seen if the cells are put in a styrofoam box and placed in either a -80°C freezer for a minimum of 2 h before transfer to the vapor phase of liquid nitrogen or left in the mechanical freezer, or directly in the vapor phase of liquid nitrogen for 30 min and then transferred to the liquid phase of liquid nitrogen. Thawing and processing is done in a similar manner to marrow cells, with dilutions performed slowly over 5–10 min using a buffered, protein-containing solution. To wash the cells free of the residual DMSO, they are centrifuged at 150g for 10 min and then gently resuspended with the same media. Cells can also be frozen in tissue culture wells for later use, e.g. lymphocytotoxicity assays.

Evaluation of cryopreserved cells

Depending on the cryoprotectant used to preserve hematopoietic stem cells, post-thaw recovery of nucleated cells varies from 50 to 90%. Unfractionated marrow cells cryopreserved in DMSO alone are associated with a lower recovery because terminally differentiated granulocytes are not successfully preserved, lyse and release nucleoproteins, causing clumping which entraps additional cells. This problem is eliminated if this cell population is removed prior to cryopreservation, or the DMSO/HES cryoprotectant is used, which successfully preserves these cells. Post-thaw recovery of committed stem cells such as CFU-GM and BFU-E also appears to be higher using the DMSO/HES method, ranging from 80 to 90% of prefreeze assays. However, post-transplant engraftment times appear similar for the two methods, with time post-transplant for a granulocyte recovery $>500 \text{ cells } \mu\text{l}^{-1}$ and platelets $>20\,000 \text{ cells } \mu\text{l}^{-1}$ of 17–22 days. Engraftment times appear to be shorter (5–7 days) for blood stem cell transplants,

largely due to the increased number of cells that are mobilized, collected and cryopreserved.

Cryopreserved lymphocytes have many uses, including histocompatibility studies, functional assays to compare differences over time or therapy given *in vivo* for determination of cell surface markers. Having a reproducible source of cells, and the ability to improve quality control by assaying all target cells at the same time under the same conditions, is of significant value. Total recovery of viable lymphocytes, cryopreserved as described above, is in the range of 70–80%, and as early as 1962 Pegg demonstrated that thawed lymphocytes could be used in stimulation assays, with little difference compared with fresh controls.

A variety of lymphocyte assays have been performed on cryopreserved lymphocytes. The relative number of B and T cells, the number of E (sheep erythrocyte) and EAC (erythrocyte–antibody–complement) rosettes, and the response to the mitogens PHA, PWM and Con A are not affected by cryopreservation but their recovery appears to be optimal when programmed freezing methods are used. The handling of the cells prior to cryopreservation appears to be important: specifically, the use of ammonium chloride is toxic to T cells when used prior to cryopreservation; it can, however, be safely used post thaw for separation studies.

Cryopreservation with DMSO appears to decrease the number and intensity of CD4^{+} , CD7^{+} , CD13^{+} and CD33^{+} cells assayed by flow cytometry, but appears to have no effect on B-lineage cells or on CD8^{+} cells. Multiple studies have demonstrated a decrease in natural killer (NK) cells, i.e. cytotoxicity against K562, as well as antibody-dependent cellular cytotoxicity (ADCC) and mixed lymphocyte responses for cryopreserved lymphocytes. NK cell recovery is 50–70% compared with that of fresh cells; however, this value significantly improves when the thawed cells are incubated for 18 hours prior to assay. Lymphokine-activated killer (LAK) cell activity may also be reduced following cryopreservation. Activity levels vary widely, ranging from 33 to 87%, depending on the effector:target ratios and the target cell line used for the assay. Cytotoxicity, however, improves upon incubation with recombinant interleukin 2 (rIL-2) for several days after thawing, and, if stimulated both before and after cryopreservation, activity levels may exceed that for fresh mononuclear cell populations due to loss of macrophage function during cryopreservation. The cause for the lowered NK and LAK activity appears to be a lowering of the binding to target cells early after thawing which recovers upon incubation for 5–24 h. Thymocyte recovery is also poor following standard

cryopreservation using DMSO but preliminary studies suggest a benefit to thymocyte recovery if both DMSO and HES are used together as cryoprotectant agents.

With the advent of many recombinant cytokines, the ability to cryopreserve both bone marrow and lymphocytes will attain even more significance. Clinical trials in which cryopreserved marrow is incubated for 24 h prior to the reinfusion into patients as part of an autologous transplant are under way.

CRYPTOCOCCOSIS, INFECTION AND IMMUNITY

Andreas Schaffner, Department of Medicine, University of Zürich, University Hospital, Zürich, Switzerland

Cryptococcosis is a chronic, subacute or rarely acute infection caused by the round encapsulated yeast, *Cryptococcus neoformans*, measuring 15–30 µm. Cryptococcal meningitis, with or without disseminated infection of other organs, is the best known form of this mycosis. Pneumonia developing after inhalation of infectious particles is more common but frequently takes a subclinical course. During fungemia the organism can lodge in the central nervous system and in any other organ system, for example skin, bone, adrenals, eyes or prostate. The central nervous system provides an immunologic sanctuary for the infection from which the fungus cannot be eradicated by host defenses. The microbiology, ecology, epidemiology and immunology of cryptococcosis have interesting aspects illustrating many important general principles of infectious diseases.

Cryptococcus neoformans is a saprophyte isolated from environments contaminated with bird (particularly pigeon) droppings and from the tree *Eucalyptus camaldulensis*. Among the four serotypes A–D serotypes A and AD from *C. neoformans* var. *neoformans* are associated with bird droppings. Ser-

otype B from *C. neoformans* var. *gattii* is associated with *E. calmadulensis* and its geographic distribution is associated with this tree, which is abundant in Australia. The ecology of serotype C, common among clinical isolates in southern California, is unknown. Serotypes A and AD are the common serotypes in clinical material from Asia, Europe and the east of the USA. Up to 5×10^7 yeast cells can be recovered from 1 g of pigeon feces. *C. neoformans* has been isolated from the environmental air in the vicinity of bird colonies but its prevalence is not comparable to the ubiquitous abundance of spores from pathogenic molds such as *Aspergillus* spp. On the other hand *C. neoformans* is more abundant in the environment than the dimorphic fungi causing endemic mycoses such as *Coccidioides immitis*, *Blastomyces dermatitidis* or *Histoplasma capsulatum*.

Before the sexual form, the perfect state *Filobasidiella neoformans* was discovered, inhalation of yeast cells, shrunk during their sojourn in hyperosmolar alkaline bird feces, was regarded as the sole mode of infection. The present view is that this assumption holds true for serotypes associated with bird drop-

pings, while the infectious particle for serotype B could well be the basidiospore of *F. neoformans*. Both the shrunken yeast, with a diameter of 3–7 μm , as well as the spore, with a diameter of 2–3 μm , are of a size that permits inhalation and deposition in the alveolar space distal to the mucociliary apparatus of the airways.

The ecology in addition to the virulence of *F. neoformans* govern the occurrence of cryptococcosis relative to other mycoses in normal and compromised hosts (Table 1). Accordingly also a positive skin test to cryptococcal in contrast to candidal antigens is commonly only found in people with exposure to bird droppings, such as pigeon breeders. *C. neoformans* takes an intermediate position between the primary pathogenic dimorphic agents of the endemic mycoses and the opportunistic molds and yeasts with regard to its virulence (Table 1). In the past, about 50% of patients with cryptococcal meningitis did not have any recognizable underlying condition explaining their vulnerability to this fungus. With the advent of the human immunodeficiency virus (HIV) epidemic, the fraction of patients without underlying disease has dwindled and the acquired immune deficiency syndrome (AIDS) is the most frequent predisposing condition, documenting the opportunistic propensities of *Cryptococcus*, particularly for patients with defective cell-mediated immunity. Cryptococcosis is the most important deep mycosis in AIDS patients and can be one of the presenting manifestations of HIV infection. It is of note that AIDS patients are not, however, particularly prone to deep-seated, invasive infections with *Candida*, *Aspergillus* or *Mucoraceae*, which, in contrast to *Cryptococcus* or the primary pathogenic agents of the endemic mycoses (Table 1),

can be controlled by phagocytic defenses alone. Clinical experience has not linked defective humoral immunity, complement deficiencies or isolated phagocytic defects to cryptococcosis.

An essential property enabling *C. neoformans* to cause human disease is its ability to grow at temperatures of 37–39°C. The elevated body temperature of mammals precludes *in vivo* propagation of nonvirulent species of *Cryptococcus*. Similarly, it appears plausible that a body temperature of 42°C explains the absence of deep-seated cryptococcosis in pigeons.

A second property essential to the virulence of *C. neoformans* is its polysaccharide capsule (Figure 1). Acapsular mutants are avirulent and by restoring encapsulation regain their virulence for mice. In analogy to encapsulated bacteria, the capsule of *C. neoformans* has antiphagocytic properties. The capsule masks binding sites recognized by phagocytic receptors for β -glucan and mannan that could mediate induction of phagocytosis and secretion of tumor necrosis factor α (TNF α). The capsule can also mask cell wall bound immunoglobulin G (IgG). Yet the capsule is also the site of complement activation via the alternate pathway, resulting in the presentation of iC3b fragments that might contribute to opsonization. Accordingly, small capsule variants can be sufficiently opsonized for phagocytosis or extracellular killing by phagocytes by the complement system alone. *In vitro* several types of leukocytes display anticryptococcal activity, including neutrophils, monocytes and natural killer (NK) cells. *In vivo* higher levels of interleukin 2 (IL-2) and interferon γ (IFN γ) are generated in response to nonencapsulated strains of *C. neoformans*. In addition it has been proposed that the polysaccharide capsule of *C. neoformans* might contribute to virulence by inducing sup-

Table 1 Comparison of *C. neoformans* with other common pathogenic fungi

Fungal pathogen	Distribution	Virulence	Infection
<i>Cryptococcus neoformans</i>	Worldwide, restricted natural habitat	Intermediate	Rare in normal host, increased incidence in AIDS patients and other compromised hosts
Monomorphic molds <i>Aspergillus fumigatus</i>	Worldwide, ubiquitous, abundant	Low	Common in host with phagocytic dysfunction
Opportunistic yeasts <i>Candida albicans</i>	Worldwide, normal endogenous flora, ecologically linked to humans	Low in regard to invasive infection	Common in compromised hosts
Dimorphic primary pathogenic fungi <i>Histoplasma capsulatum</i> <i>Coccidioides immitis</i> <i>Blastomyces dermatitidis</i> <i>Paracoccidioides brasiliensis</i>	Geographically restricted, restricted habitat	High	Common in exposed normal individuals, opportunistic propensities

Figure 1 The outstanding virulence factor of *C. neoformans* is its capsule protecting the yeast cell from recognition by phagocytes. India-ink preparation of native yeast cell in cerebrospinal fluid from a patient with cryptococcal meningitis.

pressor T cells. Antigen-specific suppressor CD8⁺ T cells produce a factor that inhibits binding of *C. neoformans* by macrophages. But while immunosuppressive mechanisms have been found to attenuate host defense mechanisms, true immunosuppression affecting the course of cryptococcosis has not been documented.

Recognition of encapsulated *C. neoformans* by antigen-specific mechanisms is the decisive element of immunity to this fungus. Natural antibody and complement have some opsonic activity, permitting phagocytosis or inhibition by alveolar macrophages of lightly or nonencapsulated variants in natural resistance, but a specific immune response is essential for an efficient control of encapsulated *C. neoformans*. Antibody-dependent inhibition or killing by phagocytes involves reactive oxygen intermediates and, in some species such as the mouse, nitric oxide. Melanin-like pigments of *C. neoformans* appear to contribute to its virulence by reducing the susceptibility of the yeast to hydrogen peroxide and nitric oxide. The anticryptococcal mechanisms responsible for the direct antifungal effect of NK and T cells against *C. neoformans* appear to be independent of oxygen or nitrogen radicals, but their nature has not been elucidated. Observations in immunodeficient

hosts make it clear that T cell-mediated immunity is essential for acquired immunity to *C. neoformans*. Athymic nude mice are unable to control an infection with this yeast and develop chronic progressive cryptococcosis; up to 8–9% of patients with AIDS go on to develop disseminated cryptococcosis. The observation that beige mice that are deficient in NK cell activity are more susceptible to cryptococcosis, but not to other fungal infections that are controlled by phagocytes alone, such as aspergillosis or invasive candidiasis, indicates that NK cells also play an important role. Extracellular inhibition of *C. neoformans* by secretory products of macrophages other than nitric oxide may also occur.

CRYPTOSPORIDIOSIS

Natural history

Cryptosporium, a protozoon found in the gastrointestinal tract of most vertebrates, was first described by Tyzzer in 1907 in the gastric mucosa of the domestic mouse. The name signifies that the parasite belongs to the class Sporozoasida in which spores are absent or concealed within the oocyst. *Cryptosporidium* is a genus which now consists of several species, of which the mammalian species *C. parvum* is the most important. *Cryptosporidium* was considered as a harmless opportunistic parasite for mammals and birds until the late 1970s, after which time evidence began to emerge implicating it as a possible cause of diarrhea in calves. The history of cryptosporidiosis in humans is more recent, the first two cases being described in 1976 by Nime *et al* and Meisel *et al*. By 1980 further cases had been described in individuals with clinical evidence of acquired or congenital immunodeficiency. The first case of cryptosporidiosis in an immunocompetent adult, who suffered severe, watery but self-limiting diarrhea and vomiting, was described in 1980 by Tzipori *et al*. This patient was the first in whom the diagnosis was made by detection of oocysts in stools. The transmission of this human isolate to mice and lambs not only showed that it was biologically indistinguishable from *Cryptosporidium* of other mammals, but also indicated indirectly the zoonotic potential of this parasite, as was subsequently confirmed by Reese and colleagues in 1982. The emergence of acquired immune deficiency syndrome (AIDS) and AIDS-related infections promoted human cryptosporidiosis to the forefront of interest in 1982. By 1985 *Cryptosporidium* had been observed in the intestines of most mammals, birds, several species of fish and reptiles. The prevalence of the infection in the general human population also became apparent with the publications of the first epidemiological studies in 1983 by Jokipii and coworkers, and Tzipori and colleagues. The early epidemiologic studies were followed by numerous reports from around the globe which established the parasite as an important cause of diarrhea in healthy and in immunodeficient individuals.

Characteristics of the organism

Cryptosporidium is a genus in the family Cryptosporidiidae, suborder Eimeriorina, order Eucoccidiorida, subclass Coccidiasina, class Sporozoasida, phylum Apicomplexa. Other important members of the suborder Eimeriorina include *Eimeria*, *Isospora*, *Toxoplasma* and *Sarcocystis*. Until 1980 *Cryptosporium* was considered to be host specific and was named after the animal species from which it was isolated. At present two mammalian species *C. muris* and *C. parvum* are recognized, the latter being the most commonly isolated from humans and domestic animals. *C. baileyi* is the only other confirmed species, infecting chickens and turkeys; others undoubtedly will emerge in the future.

The life cycle of *C. parvum* follows closely the pattern characteristic of other coccidia: asexual followed by sexual endogenous stages resulting in production and discharge of oocysts in the feces. The oocysts, however, are minute (approximately 4 µm), surrounded by a thick and extremely resistant capsule, and are shed sporulated and therefore infectious. Immediate sporulation and the fact that a portion of oocysts are produced with a thin capsule which breaks up within the host, releasing naked infectious sporozoites, contribute to the parasite's unique potential for autoinfection; a crucial phenomenon in the pathogenesis of persistent infection in immunologically compromised hosts.

Unlike other enteric coccidia, *C. parvum* does not become internalized within the epithelial cell cytoplasm but remains physically located on the cell surface. After excystation in the stomach or the duodenum, sporozoites and later merozoites become attached to the epithelial cell surface, displacing the microvillous border, and become enveloped by a membrane (parasitophore) which is derived from the host cell (Figure 1), a phenomenon termed by Gocbel and Braendler in 1982 as 'intracellular-extracytoplasmic'. By becoming internalized the parasite not only now derives all its nutrient and energy requirements from the host cell, but also evades the host immune response.

Infection and disease

C. parvum infection is extremely common in nature among domesticated and wild mammalian species.

Figure 1 An ultrathin section of ileum from a lamb experimentally infected with *Cryptosporidium*. Note endogenous forms firmly attached to the luminal surface of enterocytes displacing the microvillus border. MA represents two macrogamonts—female forms—each containing one macrogamete; MI represents a microgamont—the male form—which contains five visible, of 16, microgametes. Mi is a single microgamete, while all the others are trophozoites (the asexual form) at various stages of development ($\times 12750$).

The infection can cause disease in many species of animals, particularly in the very young and in the immunocompromised host; however, it is most commonly associated with diarrhea in humans and newborn ruminants. *C. baileyi*, the avian species, often causes respiratory symptoms in turkeys and chick-

ens. *C. parvum* infection in newborn rodents and other laboratory animals is largely asymptomatic.

Cross-transmission experiments among animal species, and reports of several cases of human infection contracted from animals, indicate that the majority of isolates perpetuating among humans,

their domestic animals and their immediate environment are interchangeable and probably belong to the genus *C. parvum*. Avian isolates (*C. baileyi*) were shown to differ on the basis of cross-transmission studies, sporozoite chromosomal DNA and some antigenic variation in the oocyst wall.

C. parvum has been observed in part or in all of the gastrointestinal tract, including the biliary system and bile duct, gallbladder, colon and rectum. The mechanism by which it induces diarrhea is not entirely clear. The endogenous stages, which heavily colonize the surface epithelium, destroy the microvillous border, leading, in the proximal small intestine, to loss of membrane-bound digestive enzymes. There is also a variable degree of villous contraction and increased cellularity in the lamina propria, both of which contribute to reduced absorption from the lumen. In humans at least, there is clinical and physiologic evidence to implicate the action of an enterotoxin in the pathogenesis of what essentially is a watery diarrhea.

While the prevalence of the infection in the general population is high, the incidence of diarrhea associated with cryptosporidiosis is 4–7% in children under 5 years of age. In infants it can be as high as 25% in outbreaks in daycare centers, and at certain times of the year in children in some African countries. The incidence is highest during the summer dry months. Oral-fecal is the most common mode of transmission – from other persons, from domestic pets and wild animals, and from contaminated water. Recently several major waterborne outbreaks of diarrhea due to *C. parvum* have highlighted water contamination as a major vehicle for exposure. The diarrheal outbreak in 1993 in Milwaukee, Wisconsin, USA, involving some 403 000 people, was a major turning point with regard to *C. parvum* in municipal water supply. Aerosol transmission may also be a factor because infection of the upper respiratory tract in humans has also been described.

The immune status of the host appears to be a major determinant of whether the infection is self-limiting or becomes persistent. It is clear that both branches of the immune system are required for complete recovery because CD4 blood lymphocyte counts below 200 per mm³, as seen in AIDS or hypogammaglobulinemia, can both lead to persistent infection. Because of the continuing increase in the incidence of AIDS, the occurrence of persistent *C. parvum* infection in this subpopulation has substantially increased.

Studies on serum antibodies against sporozoites identified the presence of antibodies to a common 20 kDa antigen – a major sporozoite surface determinant – in humans, horses and calves for up to 5

months after infection; however, levels remained high in individuals which had frequent exposure. Studies in mice have shown that passive antibodies from previously infected mothers did not prevent experimental infection; nor did treatment with monoclonal antibody against sporozoites prevent infection in mice, although there was a reduction of parasite load compared with control animals. However, bovine hyperimmune colostrum containing specific antibodies did modify the clinical outcome of infection in humans and when tested in mice. These studies indicate that high levels of antibody may be effective in reducing the infectivity of sporozoites, presumably by blocking surface receptors, but not sufficient to prevent or eliminate an existing infection. As the majority of endogenous forms are masked by a host-derived parasitophore, presumably only the free forms (sporozoites and merozoites) are exposed to host defenses.

Diagnosis

Cryptosporidiosis causing self-limiting illness is clinically indistinguishable from other forms of diarrhea and therefore diagnostic procedures are required to demonstrate an infection. *C. parvum* infection should be considered in all cases of persistent diarrhea, with or without evidence of immunodeficiency, particularly in malnourished children. Demonstration of oocysts in stools stained with modified acid-fast, remains the simplest, cheapest and the most rapid procedure. The much smaller size of the *C. parvum* oocyst, compared with other enteric coccidia, often makes the diagnosis difficult to an untrained person. The production of monoclonal antibody against various components of the oocyst wall has facilitated the development of immunofluorescence assays. These assays, now available commercially, are useful for screening morphologically damaged, excysted or nonviable oocysts. Recently several laboratories have described polymerase chain reaction (PCR) techniques which make diagnosis rapid, sensitive and specific – and safe, as they can be applied to formalin-fixed stools.

Laboratory cultivation

C. parvum has been propagated successfully in most laboratory animals and to a lesser extent in chick embryos. In cell culture the growth is restricted to a limited number of cycles and decreased yield. Persistent, asymptomatic infection can be induced in immunodeficient mice such as the nude or the severe combined immunodeficient (SCID) mouse, or after prolonged treatment with immunosuppressive drugs.

Such animals have been used to test the efficacy of therapeutic drugs. Drugs can also be tested in diarrhea models such as gnotobiotic piglets and calves, which are more expensive models than rodents.

Treatment

An effective treatment against cryptosporidiosis will undoubtedly be beneficial for humans and calves. It would greatly benefit individuals with AIDS, in whom *C. parvum* infection can be life threatening. So far, however, attempted chemotherapy in animals and humans has been disappointing. Treatment of the infection in AIDS with either hyperimmune bovine colostrum or paromomycin has produced mixed results.

Immunology

While the incidence of the disease in the general human population does not warrant the development of a vaccine, prevention of the disease in AIDS with repeated mucosal immunizations may be beneficial. Prevention of *C. parvum* infection via effective passive transfer of maternal antibody from mother to calf will be economically enormously beneficial to the cattle industry. However, the development of effective vaccines or immunotherapy require knowledge of the immune mechanisms responsible for clearance of infection and prevention of reinfection, including identification of the key parasite antigens responsible for stimulating protective immunity. Our knowledge on the host immune response to *C. parvum* infection is still very limited. The increased severity and duration of illness observed in immunosuppressed animals or immunodeficient individuals indicate that resistance to, and resolution of, *C. parvum* infection requires activation of a parasite-specific mucosal immune response in the host. Studies with adoptive transfer of *C. parvum*-immune histocompatible cells results in complete elimination of infection. Administration of cytolytic anti-CD4⁺ and/or interferon γ (IFN γ)-specific monoclonal antibodies provides evidence that IFN γ may act to limit the level of infection, while CD4⁺ T cells may limit the duration of infection. The significant role of CD4⁺ T cells is further supported by the enhanced susceptibility to *C. parvum* of major histocompatibility complex (MHC) class II-deficient mice which fail to develop CD4⁺ T cells. The role of CD8⁺ T cells, which also produce IFN γ , remains unresolved. While IFN γ and CD4⁺ are both important in establishing resistance to, and resolution of, *C. parvum*

infection, precisely how this occurs is unknown. Recently it was shown that administration of interleukin 12 (IL-12), which activates natural killer cells and cytotoxic T lymphocytes and stimulates IFN γ production, prevented *C. parvum* infection in mice. It provided the first evidence that treatment with exogenous IL-12 can prevent *C. parvum* infection by an IFN γ -dependent, specific immune system-independent mechanism, and that endogenous IL-12 production has a role in limiting *C. parvum* infection.

In summary, much more information is now available on the epidemiology and transmission of the infection, and on the nature of the disease in humans and in other mammals, *C. parvum*, however, remains enigmatic from the point of view of its biological characteristics, and, for a life-threatening disease in individuals with AIDS, the infection remains untreatable. This is despite concerted efforts by scientists to develop an effective immunotherapeutic and/or chemotherapeutic treatment. Important issues that remain unresolved include understanding the underlying mechanisms of attachment of the parasite to cell receptors and of diarrhea, and defining the immune mechanisms required to either resist, or resolve, *C. parvum* infection.

CUTANEOUS ANAPHYLAXIS

Malcolm HA Rustin and **Catherine H Orteu**, Department of Dermatology, The Royal Free Hospital, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In 1902, Portier and Richet injected foreign protein into animals without incident, but found that when injected a second time a fatal systemic reaction was induced. The phenomenon was called anaphylaxis and may be defined as a specific immunoglobulin E (IgE)-mediated antigen-induced reaction by mast cells and basophils, the type 1 immediate hypersensitivity reaction of Gell and Coombs. Clinically, the term anaphylaxis is used to describe a syndrome resulting from the release of a variety of preformed and newly generated, mast cell-derived chemical mediators (**Table 1**). The trigger may be mediated by specific antibodies such as IgE, or by nonimmunologic mechanisms. The hallmarks of a cutaneous anaphylactic reaction are urticaria and angioedema and such a reaction may remain localized to the skin, or become generalized, causing pruritus, diffuse erythema, urticaria, angioedema, laryngeal edema, bronchoconstriction, hypotension and cardiac arrhythmias. In addition, the skin may either be the source of an anaphylactic reaction, or be a target organ in a systemic reaction. Causes of systemic anaphylaxis in which the skin is the origin of the reaction are listed in **Table 2**.

Table 1 Mediators released from activated mast cells

Preformed mediators
Histamine, heparin, tryptase, kininogenase, carboxypeptidase A
Proteoglycans, eosinophil and neutrophil chemotactic factors
Newly generated mediators
Prostaglandin D ₂ , thromboxane A ₂
Leukotriene B ₄ , C ₄ , D ₄ and E ₄
Platelet-activating factor
Cytokines
Interleukin 3,4,5,6
Granulocyte-macrophage colony-stimulating factor

Table 2 Causes of cutaneous anaphylaxis

Immediate wheal and flare prick test responses
Insect stings or bites
Immunologic contact urticaria
Physical urticaria: cold, aquagenic, solar, cholinergic, delayed pressure

Urticaria

Data on the prevalence of urticaria are few, but it is thought to affect 15–23% of the general population. It is an eruption caused by exudation of fluid into the dermis which presents as itchy, erythematous or edematous swellings known as wheals, surrounded by a bright red flare (**Figure 1**). Clearing of the central area may result in an annular pattern and lesions vary in size from 2–5 mm up to several centimeters in diameter (**Figure 2**). They may occur anywhere on the skin and usually last between 12 and 24 h. In angioedema the edema extends subcutaneously or submucosally and swellings are larger, usually not itchy and may last up to 72 h. It most commonly affects the eyelids, lips and tongue, but any part of the body may be affected. Urticaria and angioedema occur together in nearly 50% of patients and both fade, leaving completely normal skin. There are many causes of urticaria (**Table 3**) but the end-result is a release of mediators that cause increased permeability of capillaries and small venules.

Urticaria is traditionally divided into acute and chronic forms (**Table 4**). Acute urticaria may be idiopathic, IgE mediated, or result from nonimmunologically mediated reactions. The latter may be anaphylactoid reactions, or be due to direct mast cell activation or to altered arachidonic acid or kinin metabolism.

Chronic urticaria is arbitrarily defined as the occurrence of widespread wheals daily, or almost daily, for at least 6 weeks. It is idiopathic in approxi-

Figure 1 Acute urticaria with marked erythema and whealing. (See also color **Plate 7A**.)

Figure 2 Urticaria showing central clearing and an annular pattern. (See also color **Plate 7B**.)

mately 75% of patients, and caused by physical stimuli in a further 15% of patients. In the past, it was suggested that up to 30% of patients with chronic urticaria reacted to food additives such as benzoic acid compounds, azo dyes and penicillins; more recently, in a placebo-controlled oral challenge study, Kobza Black and colleagues found an incidence of no more than 10%. Such reactions may be more common in children and, if the history is suggestive, appropriate challenge testing is justified. Other exacerbating factors include aspirin (in 30%), psychological stress, intercurrent febrile illness and, more rarely, parasitic infestations. Urticarial vasculitis is an important differential diagnosis and, if suspected, a skin biopsy should be performed. A prolonged history of repeated cutaneous or mucosal angioedema should prompt screening for hereditary or acquired C1 esterase deficiency by measuring plasma complement C4 levels.

Nonsedating H_1 antihistamines are the mainstay of treatment in urticaria. A number of drugs are available, namely terfenadine, cetirizine, astemizole, acrivastine and loratidine. Terfenadine and astemizole are extensively metabolized by cytochrome P450 and can produce elongation of the Q-T interval and arrhythmias in susceptible patients. In view of this, recommended doses should not be exceeded and they should never be prescribed together or in conjunction

Table 3 Classification of urticarias according to underlying mechanism

Immunologic
IgE mediated
Foods: fish, shellfish, milk, eggs, nuts, fruit, vegetables, spices
Drugs: penicillin, porcine insulin, dextran
Insect stings: bees, wasps, hornets, yellow jackets
Inhalants: pollens, animal dander
Contactants: latex
Physical: dermatographism, cold, solar, cholinergic
IgG autoantibodies to high-affinity IgE receptor or IgE or both
Immune complex/anaphylatoxin-mediated
Urticarial vasculitis
SLE, Sjögrens syndrome, hepatitis B or C, serum sickness, drugs, IgM gammopathy
Blood products
Radiocontrast media
Haptens
penicillins, cephalosporins, sulphonamides, tetracyclines, macrolides
Non-immunologic
Direct mast cell activators
Opiates, tubocurarine, radiocontrast media, dextran, polymyxin
Arachidonic acid metabolism
Aspirin, non steroidal anti-inflammatory drugs (NSAIDs)
Kinin metabolism
Angiotensin converting enzyme (ACE) inhibitors
Idiopathic
Miscellaneous
Physical: heat, vibratory, delayed pressure, aquagenic
Thyroid autoimmunity

Table 4 Classification of urticarias

Acute
Idiopathic
IgE mediated:
Immediate wheal and flare prick test response
Insect stings, penicillin,
Transfusion of blood or blood products
Fish, shellfish, milk, nuts, vegetables, fruit, spices
Nonimmunologically mediated:
Aspirin, NSAIDs, paracetamol, radiocontrast media, dextran, food dyes, preservatives, morphine, codeine, tubocurarine
Chronic
Idiopathic
IgG autoantibodies to high-affinity IgE receptor or IgE or both
Contact urticaria
Immunologic
Nonimmunologic
Physical urticaria
Dermographism, delayed pressure urticaria, cholinergic urticaria, cold urticaria, aquagenic urticaria, solar urticaria
Urticarial vasculitis

with drugs such as cyclosporine, erythromycin or ketoconazole. With astemizole adequate contraception is essential during treatment and for up to 4 weeks afterwards. Older, more sedating H₁ antihistamines, such as chlorpheniramine or hydroxyzine, can be used concurrently and may be useful to alleviate pruritus at night. If one particular compound is not effective, others should be tried sequentially as there is a wide variation in response between patients. There is also a variability of response to different antihistamines over time, largely as a result of tachyphylaxis, and breaks from or changes in treatment may be beneficial. The role of H₂ antihistamines is controversial. There is some evidence that in combination with H₁ antihistamines they are of benefit in some patients with symptomatic dermatographism and chronic idiopathic urticaria. Ranitidine is the drug of choice as it does not inhibit cytochrome P450 or seem to have the pronounced antiandrogenic effects of cimetidine with long-term use.

Immediate wheal and flare prick test responses

Prick testing involves the application of commercially prepared diluted antigens as single drops on marked areas of skin on the forearm. The skin is gently pricked through the drop and the drop is then removed with a tissue wipe. The wheal starts within 10 min, reaches a peak within 20–30 min and resolves in 1–2 h. It depends upon the reaction and cross-linking of antigens with specific IgE antibody bound through its Fc to mast cells and basophils. Rarely, prick tests may precipitate a systemic anaphylactic reaction.

Insect bites and stings

Allergic reactions to insect stings may occur as extensive localized swelling (>10 cm in diameter) lasting at least 24 h, immediate IgE-mediated systemic reactions (urticaria, angioedema, bronchospasm and anaphylactic shock) or more rarely as delayed systemic reactions (vasculitis, polyradiculitis, glomerulonephritis). The prevalence of such reactions varies from 3.1–17% for extensive localized to 0.15–3.3% for systemic reactions. The diagnosis is suggested by the history and the Hymenoptera most often implicated include Apidae (the honeybee and bumblebee), Vespidae (wasps, hornets and yellow jackets) and Myrmicidae (stinging ants). The major allergens in venom are different forms of phospholipase A. In addition, bee venom contains enzymes (acid phosphatase and hyaluronidase), mediators (dopamine and norepinephrine) and peptide 401, which causes mast cell degranulation. Similar toxins are present in wasp venoms. The most sensitive techniques for determining the presence of

venom-specific IgE antibody (i.e. sensitization) are the radioallergosorbent test (RAST) and skin testing with venoms. Such tests are positive in 15–25% of the general population, presumably reflecting normal IgE responses to insect stings in nonallergic subjects. A positive RAST does not discriminate between those patients who develop a local rather than a systemic anaphylactic reaction, and up to 2% of patients with anaphylactic reactions may have negative tests. A majority of patients with large local reactions will continue to have localized reactions regardless of their IgE status, although 5–10% of adults and 2% of children may have systemic reactions following a subsequent sting. The risk of systemic reactions on re-sting in patients with a previous systemic reaction is 29% and is usually of similar severity to the previous systemic reaction in adults and similar or less severe in children. Systemic reactions are more likely to be severe following bee stings (which contain a larger dose of venom than wasp stings), or if re-sting occurs >2–3 weeks and <10 years after a previous sting. Immunization with venom is a safe, extremely effective treatment for preventing future systemic reactions and the aim of such immunization is to increase venom-specific IgG levels and to produce negative skin tests and RAST. Such treatment is mandatory in patients with a history of severe systemic reactions and can be undertaken for milder systemic reactions in adults and children if appropriate. It is not recommended for large local reactions which respond to treatment with nonsedating H₁ antihistamines. In the event of a severe systemic reaction, treatment should be with epinephrine and antihistamines, as for systemic anaphylaxis (see below).

Contact urticaria

This is a localized wheal and flare response, usually occurring within minutes and provoked by the application of a wide range of rapidly absorbable agents to the skin, lips and buccal mucosa. Contact urticaria may occur through immunologic or nonimmunologic mechanisms.

Immunologic contact urticaria Immunologic contact urticaria is distinguishable by its ability to involve other organ systems and its increased prevalence in atopic individuals. It is due to a type I IgE-mediated hypersensitivity and so patients have positive RAST and skin prick tests to the contactant allergen, most of which are proteins or protein complexes. As systemic reactions can occur with skin prick testing in such patients, other tests are often undertaken: casual handling of the suspected provoking agent in exactly the same way as when the symptoms appear and open or occlusive patch testing

(in which the substance is applied to uninvolved skin for 15 minutes either with or without occlusion).

Foods Foodstuffs are common causes, and this type of reaction is common in food handlers who may present with a true contact urticaria or recalcitrant hand eczema (with immediate exacerbations when affected skin is exposed to the responsible food proteins). Common allergens include wheat flour, chicken, turkey, lamb, fish, shellfish, garlic, onions, chives, cucumber, horseradish, leek, parsley, tomato, lettuce, endive, apple and potato.

Some patients experience itching, tingling and/or edema of the lips and tongue and hoarseness, occasionally progressing to systemic symptoms following contact of fruit and vegetables, particularly apple, carrot, parsnip and potato, with the orolaryngeal area. This is particularly common in atopics with hypersensitivity to birch pollen and, in such cases, is thought to be due to cross-reactivity of polypeptide fruit and vegetable allergens with birch allergens.

Latex Although the predominant immunologic response (in 82% of cases) to natural rubber latex is a type IV delayed hypersensitivity to rubber additives which presents as contact dermatitis, IgE-mediated immunologic contact urticaria and anaphylactic reactions are well recognized. IgE antibody to residual rubber tree proteins in latex medical devices are present in 7–10% of nonatopic health care workers. Sensitization usually occurs as a result of regular latex exposure from wearing gloves or inhaling aerosolized latex in the workplace. In children with spina bifida the prevalence ranges from 28 to 67%, presumably as a result of mucosal absorption of latex allergens during multiple surgical procedures early in life. Exposure to latex gloves during surgery, gynecologic examination or dental procedures, and in men use of latex condoms, have also been implicated. Re-exposure of such individuals may lead to contact urticaria and/or systemic reactions such as allergic rhinoconjunctivitis, asthma or anaphylactic shock. Diagnosis is made on positive RAST or skin prick testing, however the latter appears to have an increased risk of anaphylactic reactions and should be performed with very dilute (1:1 million) doses of commercially available extracts. Treatment is by avoidance of latex-containing materials and, in particular, the complete removal of powdered latex gloves from the environment; this dramatically reduces the amount of aerosolized latex particles.

Many other agents are capable of producing immunologically mediated contact urticaria, including drugs; (particularly antibiotics, e.g. penicillin,

cephalosporins, neomycin, chloramphenicol), metals (e.g. nickel), animal hair and dander, textiles and cosmetics.

Nonimmunologic contact urticaria This type of contact urticaria is much more common than the immunologic variety. Its mechanisms are less well understood, although direct effects on vascular endothelium or non-antibody-mediated release of prostaglandins, leukotrienes and other inflammatory mediators have been suggested. Prior sensitization is not required. Common precipitants include salicylates, parabens, sulfites, benzoic acid, sorbic acid, cinnamic acid, cinnamic aldehyde and nicotinic acid esters present in foods, such as ice cream and chewing gum, shampoos, perfumes, mouthwashes, creams and ointments. Plants such as nettles, primula and seaweed, as well as moths, caterpillars, sea anemones, corals and jellyfish may also be responsible. Symptoms remain localized and include burning, stinging, itching, edema and erythema. Skin prick testing results often do not correlate with clinical findings and should be considered in conjunction with the history. Oral challenge testing is not performed routinely, but can be done on a placebo-controlled basis if the history is suggestive. It should not be undertaken in patients with a history of severe angioedema, asthma or systemic anaphylaxis. Sixteen different food additives, alternating with placebo, are administered on a daily basis. The patient keeps a daily diary of wheal counts and continues the usual dose of antihistamine if this has already been prescribed. If an exacerbation of urticaria occurs within 24 h of the ingestion of a numbered capsule, the potential culprit is administered once more to confirm the findings.

Chronic idiopathic urticaria

Up to 75% of patients seen with urticaria in dermatology clinics have chronic idiopathic urticaria, lasting more than 6 weeks. Clinically it resembles acute urticaria, usually occurs in adults and is twice as common in women. It frequently follows a relapsing-remitting course and up to 40% of patients who have chronic urticaria for over 6 months still have lesions 10 years later. It frequently occurs in association with physical urticarias, particularly symptomatic dermographism and delayed pressure urticaria. Appropriate challenge testing should be performed in such patients to assess the predominant cause of their symptoms. Autoimmune thyroid disease occurs in 14% of patients and recent studies have suggested an autoimmune basis for chronic idiopathic urticaria. In up to 60% of patients an endogenous histamine-releasing factor has been identified. IgG auto-

antibodies causing mast cell degranulation have been found in nearly half of these patients: anti-IgE, anti-FcεRIα (directed against the α subunit of the high-affinity IgE receptor expressed by basophils and mast cells) and a further antibody thought to interact with FcεRI but not FcεRIα. These findings have therapeutic implications and in patients with autoantibodies and severe disease unresponsive to conventional therapy, plasmapheresis, intravenous immunoglobulin and cyclosporine have induced remissions. Nonsedating H₁ antihistamines remain the first-line treatment. Sedating antihistamines may be added if symptoms are troublesome at night. Doxepin (10 mg three times daily or 25 mg at night), which, in addition to its tricyclic antidepressant activity, is a potent H₁ antagonist, a weak H₂ antagonist and a weak muscarinic agonist, is useful in patients with associated anxiety or depression. Doxepin should not be given with monoamine oxidase inhibitors or terfenadine. The addition of H₂ antihistamines to H₁ antihistamines can produce additional benefit in some patients. Patients should avoid aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme inhibitors, which may all aggravate symptoms. A salicylate-free diet may be of benefit and a 4 week trial of a strict exclusion diet can be performed to assess this.

Urticarial vasculitis

This disorder presents clinically as urticaria but histopathologically the features are those of a cutaneous leukocytoclastic vasculitis of variable degree. It may be impossible, clinically, to differentiate ordinary urticaria from urticarial vasculitis but important pointers include a longer duration of lesions (up to 3–7 days), a burning or painful sensation at the site of lesions and the fact that lesions may resolve with residual purpura, bruising or scaling. Frankly vasculitic or bullous lesions may rarely occur. In addition, there may be evidence of a systemic vasculitis with fever, arthralgia and more rarely arthritis, glomerulonephritis, obstructive pulmonary disease or gastrointestinal, ophthalmic or central nervous system involvement. Many patients are hypocomplementemic and in some an IgG autoantibody to C1q has been demonstrated. In others, the pathogenesis is that of an immune-complex vasculitis resembling a type III hypersensitivity. The antigen involved is unknown in most cases, although patients with serum sickness, the collagen-vascular diseases systemic lupus erythematosus and Sjögrens syndrome, and infections such as hepatitis B and infectious mononucleosis may present with this clinical picture. Treatment with H₁ antihistamines alone or in combination with H₂ antihistamines is only

rarely of benefit. Additional therapy with dapsone, hydroxychloroquine, sulfasalazine, NSAIDs, systemic corticosteroids or azathioprine may be required.

Physical urticaria

In the physical urticarias, specific physical stimuli trigger mast cell degranulation, with the release of mediators. In some cases there is evidence of a passively transferable reactivity which is thought to involve IgE, or more rarely, IgM or IgA, recognizing a molecule released or conformationally altered by the physical stimulus. Often more than one type coexists in the same patient, suggesting abnormal tolerance of self antigens.

Dermographism Simple dermographism is a transient erythematous and whealing response which develops in 5% of the population after application of only a moderate pressure to the skin. It appears to represent a combined effect of pressure and shearing forces on the skin and is therefore an exaggerated triple response of Lewis. In symptomatic dermographism, the threshold to induce dermographism is lowered and there is marked pruritus (**Figure 3**). Lesions may be precipitated by the pressure caused by the elastic in underwear or from shower jets. Symptomatic dermographism is more common in young adults (mean age of onset 26 years) and is not associated with atopy. The diagnosis can be confirmed using a calibrated dermographometer. It may last for months or indefinitely. Treatment with the nonsedative H₁ antihistamines usually provides good symptomatic relief, cetirizine and astemizole being the most effective. Addition of an H₂ antihistamine may be of benefit in this group.

Delayed pressure urticaria This type of urticaria often occurs in association with chronic idiopathic

Figure 3 Symptomatic dermographism, marked linear whealing has occurred at sites of scratching. (See also color Plate 7C.)

urticaria. There is erythema, dermal and subcutaneous edema developing 4–6 hours after application of sustained pressure perpendicular to the skin. Lesions occur after activities such as climbing ladders, walking or sitting on a hard surface, carrying heavy items, wearing tight-fitting clothes, using a screwdriver or hammer or after kissing or sexual intercourse. Maximum swelling occurs after 10 h and the lesions may last up to 48 h. Patients often complain of itching and a painful or burning sensation in the lesions; generalized symptoms of malaise, fever, headache or generalized arthralgia occur in about 70% of patients. The diagnosis is confirmed using a calibrated dermatographometer. Cetirizine (10 mg daily) is now the treatment of choice. It is the only H_1 antihistamine of any proven value, presumably because it also inhibits eosinophil and neutrophil chemotaxis. Stanazolol (2.5 mg daily) and dapsone (50–100 mg daily) are of benefit in some patients, although their mechanisms of action are unclear.

Cholinergic urticaria This urticarial eruption occurs in situations where there is activation of cholinergic sympathetic autonomic nerve fibers supplying eccrine sweat glands, after exercising or hot baths, or during periods of mental stress or anxiety. The itchy lesions are 2–5 mm diameter monomorphic wheals surrounded by a bright red flare which lasts no more than 20 min to 1 h. In some cases angioedema, flushing, faintness, bronchospasm or hypotension may occur. Cholinergic urticaria may be induced by intradermal injections of acetylcholine and can be abolished by local anesthetics and topical applications of atropine. The exact pathogenesis is unknown. The diagnosis is confirmed by reproduction of the eruption by exercising sufficiently to cause sweating or by immersion in bath water at 42°C for 10–15 min. Treatment with nonsedating H_1 antihistamines, either continuously or before an activity known to precipitate urticaria, is recommended. Danazol has also been reported to be effective. It raises protease inhibitor levels and clinical improvement can persist for several months after cessation of treatment. The condition may last for months or years and then spontaneously resolve.

Cold urticaria This urticaria develops after exposure of the skin to cold and may be idiopathic or secondary to serologic abnormalities. The majority of patients with the idiopathic form (over 90%) have the primary acquired form of cold urticaria.

A. Idiopathic cold urticaria

Primary acquired cold urticaria This occurs 5–30 min after exposure to cold and may be precipitated by wind, cold bathing, handling cold objects, immersion of the hands in cold water, and drinking cold foods or drinks. The urticaria may develop during the period of exposure but more often develops during rewarming. It lasts for about 30 min and resolves, to leave normal appearing skin. In up to 50% of patients systemic symptoms may occur, characterized by syncope, headache, palpitations and wheezing. Loss of consciousness and drowning may occur during swimming. The diagnosis can be confirmed by the induction of lesions by the application of a polythene-wrapped ice cube to the skin for 5–10 min with a 5 min period allowed for rewarming.

Rarer forms of primary acquired cold urticaria:

1) delayed cold urticaria – lesions occur several hours after exposure; 2) localized cold urticaria – lesions occur at sites of injections and bites; 3) reflex cold urticaria – widespread whealing occurs in response to a fall in core temperature.

Familial cold urticaria This is rare and is inherited as an autosomal dominant condition. It starts at an early age and is a lifelong problem. Urticaria develops 30 min after patients are exposed to generalized cooling rather than local cold application, and lesions may persist for up to 48 h.

B. Secondary cold urticaria This type accounts for about 5% of all patients with cold urticaria and may occur in association with cryoglobulinemia, cryofibrinogenemia and cold hemolysins. Other triggering factors such as viral infection, syphilis, infestations or allergies to drugs, such as penicillin, oral contraceptives and griseofulvin, can sometimes be identified.

The pathophysiology of cold urticaria is unclear but between 10 and 50% of patients with primary acquired cold urticaria demonstrate the phenomenon of passive transfer by a serum factor which may be either IgE or IgM. The mainstay of treatment is the avoidance of precipitating factors, but nonsedating H_1 antihistamines may be required. Ketotifen (2–4 mg daily), which is both an H_1 antihistamine and a mast cell stabilizer, and doxepin (10–25 mg three times daily) are both effective. Finally, induction of cold tolerance by repeated cold exposure may be attempted but this usually involves taking one or two cold showers or baths a day and requires that patients be strongly motivated.

Aquagenic urticaria Contact with water, irrespective of its temperature, may induce an urticarial eruption which looks very similar to cholinergic urticaria. The lesions are frequently confined to the neck, arms and upper trunk, develop within 5–30 min of exposure to water and resolve over the next hour. The condition is partly responsive to antihistamine therapy with terfenadine, cetirizine or loratidine (10 mg daily) and barrier preparations may be used for aquatic sports.

Solar urticaria This is an uncommon condition in which urticaria develops within 2–3 min of sun exposure and then fades within an hour or so. It occurs particularly in areas of exposed skin which are usually kept covered. All parts of the ultraviolet light spectrum may induce solar urticaria. Passive and reverse passive transfer tests have been demonstrated in such patients. A precursor is converted to an antigenic photoproduct which triggers an IgE-mediated response and the diagnosis is confirmed by monochromator or solar stimulator testing. Treatment is often disappointing as only in the mildest cases are sunscreens beneficial, and, with the exception of astemizole (a highly specific H_1 antagonist) antihistamine therapy is usually ineffective. Tolerance may be induced by the appropriate ultraviolet source and, as the condition is due to a circulating photoallergen, plasmapheresis can be used in severely affected patients during the desensitization phase. In combination, PUVA (psoralens and ultraviolet B) and plasmapheresis produce a more prolonged improvement than if used alone.

Hereditary angioedema

This is a rare disorder, inherited as an autosomal dominant trait in which there is a deficiency in the activity of C1 esterase inhibitor, resulting in continued complement activation. There is usually a family history, although not invariably, and it usually presents in early childhood but may be delayed until late adult life. Patients present with nonitchy and sometimes painful swellings on the limbs or face, attacks of abdominal pain, vomiting and diarrhoea (which may be blood stained). The most serious manifestations are edema of the larynx, pharynx, trachea and bronchi, leading to respiratory obstruction and asphyxia in up to 30% of patients. Hypotension and urticaria are usually absent, helping to distinguish such attacks from acute, generalized anaphylaxis. Attacks may be precipitated by trauma, stress, infections or cold and usually last between 48 and 72 h, although lesions may not resolve for days or even weeks.

The diagnosis can be confirmed by the finding of low C4 and C2 levels in all patients. In type I hereditary angioedema, which accounts for 85% of patients, low functional and antigenic levels (5–31% of normal) of the C1 esterase inhibitor occur, due to decreased synthesis and increased metabolism. In the remaining 15% of patients, as a result of point mutations in the reactive center, the functional level is low but the antigenic level is within normal limits.

The treatment of choice in an acute attack is with intravenous purified C1 esterase inhibitor (24 000–36 000 units). If this is unavailable, fresh frozen plasma may be used, although, because this contains more C4 and C2, patients may initially deteriorate before they improve. In the presence of laryngeal edema, epinephrine, oxygen, H_1 antagonists and corticosteroids are also recommended (see treatment of anaphylaxis below). For prevention of recurrent attacks danazol (100–400 mg daily for 1 month, then 5 days on, 5 days off) or stanazolol (2.5–10 mg daily to control attacks then 2.5 mg three times a week), which increase hepatic synthesis of C1 esterase inhibitor, tranexamic acid (1–3 g daily), which carries a risk of thromboembolism, or epsilon aminocaproic acid may be prescribed. Patients should avoid taking angiotensin-converting enzyme inhibitors which alter kinin metabolism.

Acquired form of hereditary angioedema

In the nonhereditary form of angioedema, deficiency of the C1 esterase inhibitor occurs either as an autoimmune process in systemic lupus erythematosus or in association with hematological malignancies such as lymphoma or myeloma. In the autoimmune variety, anti-C1 esterase inhibitor antibodies predispose it to cleavage. In lymphoproliferative disease there is a 2–3-fold increase in C1 esterase inhibitor metabolism, possibly as a result of continuous activation of C1 by anti-idiotypic antibodies directed against surface immunoglobulin on the malignant B cells, leading to C1 esterase inhibitor-complex formation and removal. Characteristically, in the acquired disease C1 levels are very low, whereas in the hereditary form C1 levels are normal. Treatment is aimed at the underlying cause.

Treatment of anaphylaxis

The first-line treatment of systemic reactions, which may include bronchospasm, hypotension and angioedema, is an intramuscular injection of epinephrine in a dose of $10 \mu\text{g kg}^{-1}$ up to 1 mg (1 ml of 1:1000 solution), which may need to be repeated every 10 min until improvement occurs. Epinephrine acts as a positive inotrope, blocks the end-organ effects of

histamine, and inhibits release of histamine and leukotrienes from mast cells. Administration of high-dose oxygen is also of primary importance. Additional second-line treatment consists of H_1 antagonists, initially intravenously (chlorpheniramine 10–20 mg) and then orally (e.g. cetirizine 10 mg once daily or terfenadine 60 mg twice daily) for 24–48 h to prevent relapse, and corticosteroids (intravenous hydrocortisone 100–300 mg or 5 mg kg^{-1}), which may help suppress the late-phase and persistent responses. Continuing deterioration may necessitate treatment with bronchodilators, either nebulized or intravenous β_2 agonists (nebulized salbutamol 2.5–5 mg four times daily, intravenous salbutamol 3–20 $\mu g \text{ min}^{-1}$) or intravenous aminophylline infused slowly over 10–15 min (up to a total dose of 500 mg or 4 mg kg^{-1}). Occasionally, slow intravenous infusion of low dose adrenaline (5 ml of 1:10 000 adrenaline at a rate of 1 ml = 100 $\mu g \text{ min}^{-1}$ until improvement occurs) is required. Fluid replacement with colloids such as hemacel, monitoring of central venous pressure (CVP) and/or pulmonary capillary wedge pressure (PCWP) and in the presence of a raised CVP or PCWP, inotropic support with dopamine (5 $\mu g \text{ kg}^{-1} \text{ min}^{-1}$) and occasionally norepinephrine may be necessary. The use of H_2 antagonists is controversial, but it has been suggested that in combination with H_1 antagonists these agents suppress late-phase cutaneous responses.

For patients with previous or recurrent anaphylactic reactions, for example to bee stings, emergency self-treatment kits are available (e.g. Epipen which contains 300 μg epinephrine in a fully assembled syringe) and patients should be taught to give their own injections. Epinephrine inhalations (e.g. Medi-haler-Epi which contains 280 μg per metered inhalation – adults should take a minimum of 20 puffs) are much less effective but may be useful in patients without other symptoms who are beginning to develop bronchospasm or edema in the orolaryngeal area.

CYCLOSPORINE

Jean F Borel, Götz Baumann and Thomas Beveridge, Sandoz Pharma Ltd, Basel, Switzerland

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Ciclosporin (WHO)/cyclosporine (US Adopted Name Council)/cyclosporin A (British Approved Name) (CsA) is a cyclic undecapeptide containing a novel amino acid together with several *N*-methylated amino acids, which is produced as a major secondary metabolite of the fungus *Tolypocladium inflatum* Gams. This strain of fungi imperfecti was isolated from a soil sample collected in the Hardanger Vidda (Norway). Extracts of cultures exhibit a narrow spectrum of antifungal activities *in vitro*, but exert only limited effects *in vivo*. The striking selective immunosuppressive activity discovered in 1972, in an additional pharmacological screening, led to an extensive investigation of this fungal metabolite. CsA is the first immunosuppressive drug to selectively and reversibly act only on a limited population of lymphocytes and to be devoid of myelotoxicity. This explains its immediate impact in the field of transplantation. Today, however, its potential in the treatment of autoimmune diseases is steadily growing. CsA is also widely used as an experimental probe in basic research.

Pharmacology of CsA

The structure of CsA (Figure 1) was established by chemical degradation and X-ray analysis of an iodo-

derivative. Having a molecular weight of 1202, $C_{62}H_{111}N_{11}O_{12}$, CsA is a neutral, hydrophobic, cyclic peptide with 11 amino acid residues, all having the *L*-configuration of the natural amino acids, except for the *D*-alanine in position 8 and the achiral sarcosine in position 3. One amino acid had never been seen before. Located in position 1, it is abbreviated as MeBmt, for (4*R*)-4-[(*E*)-2-butenyl]-4, *N*-dimethyl-*L*-threonine.

The molecular mechanism of action of CsA in the antigen-driven T cell activation process is shown in Figure 2. In contrast to previous immunosuppressive drugs (mostly cytostatic drugs), CsA exerts a specific action on lymphocytes, but it does not influence the functions of phagocytes or hematopoietic stem cells. It is neither lymphocytotoxic nor mutagenic, and its action is reversible. Besides being accepted today as the first-line immunosuppressive drug for clinical use, CsA is also widely used as an experimental probe in basic research. Especially for immunologists, it has become an important pharmacologic tool for defining *in vitro* the respective roles of cell interactions and mediators in lymphocyte activation, analyzing the cell regulatory mechanism of the genes, and studying the different steps involved generally in an immune response. Though *in vitro* several pathways can lead to the induction of gene transcription in lymphocytes, only pathways involving mobilization of intracellular calcium are CsA sensitive. There is compelling evidence that CsA acts by preventing the activation of resting lymphocytes at an early stage of the cell cycle (G_0 to G_1 transition), thus inhibiting primarily the production and release of interleukin 2 and several other lymphokines by helper T cells.

CsA has been widely used *in vivo* to evaluate the contribution of various T cells not only in normal but also in pathological conditions. Since the drug can induce and maintain a remission in many models of autoimmunity as well as in clinical autoimmune diseases, it is evident that it also inhibits fully activated T cells, possibly by suppressing their continuous *de novo* restimulation. The *in vivo* mechanism of action is still being debated. However, most observations resulting from many different types of *in vivo* models suggest that CsA acts by suppressing lymphocyte activation within the allograft in transplantation or at the site of (chronic) inflammation in autoimmunity. Although necessary and often helpful, *ex*

Figure 2 General overview of T cell signaling pathways following ligation of the T cell receptor (TCR) or the IL-2 receptor (IL-2R). Mode of action of CsA. In the presence of costimulatory signals provided by multiple cell surface receptor–ligand interactions (e.g. CD28/B7-1, 2; LFA-1/ICAM; CD2/LFA-3; CD45/CD22; IL-1R/IL-1) antigen (AG) presented by an antigen-presenting cell (APC) in the context of major histocompatibility complex (MHC) proteins induces a T cell differentiation process that results ultimately in lymphokine secretion (G_0 to G_1 transition of cell cycle) and proliferation (G_1 to S) of the antigen-specific T cell. Signal transduction involves a number of biochemical events, including phosphorylation and dephosphorylation (P) of tyrosine, threonine or serine residues of intracellular signaling proteins, leading to gene transcription of 'early' genes like IL-2. CsA exerts its immunosuppressive effects downstream from the very early membrane-associated events, such as activation of phospholipase C_γ (PLC γ) and recruitment of tyrosine kinases (e.g. LCK, FYN, CSK, ZAP-70) and SHC to the 'immunoreceptor tyrosine-based activation motifs' (ITAM) in the ϵ and ζ chains of the T cell receptor (TCR)/CD3 complex. It is hypothesized that cyclophilin-bound CsA inhibits the calcium-dependent (Ca^{2+}) phosphatase activity of calcineurin (CN-A, -B and Cam, calmodulin) as a crucial step in the activation (*) and nuclear translocation of cytoplasmic transcription factor subunits like NFAT $_{c/p}$ and/or NF κ B required for 'early' gene transcription. IL-2R-mediated signaling processes involving activation of JAK kinases, STATs (signal transducers and activators of transcription), RAFTs (rapamycin and FKBP target) and p70 S6 kinase (p70 S6K) are not affected.

vivo results may be misleading, because the experimental reactions are occurring outside the organism in which CsA is present in biologically effective levels.

CsA in transplantation

CsA was first registered in 1983 (trade name Sandimmune®) for use in organ transplantation. Recently, a new microemulsion formulation of CsA (trade name Sandimmun Neoral® or Neoral®) which shows more consistent oral absorption, is bile independent, and has dose linearity, has become available. This has the advantage that its absorption is not affected by food intake and it shows reduced variability between as well as within patients. Neoral® has been shown to be safe and well tolerated.

CsA is used for the prevention of acute rejection of kidney, liver, heart, heart-lung, lung and pancreas allografts. It may also be used to treat rejection episodes in patients who have already received other immunosuppressants. In bone marrow transplantation, CsA is used to prevent rejection of the transplanted bone marrow as well as for prevention and treatment of graft-versus-host disease (GVHD). In transplantation CsA has long become established in all drug regimens and is today the drug of first choice in immunosuppression. However, it is seldom used alone but generally in combination with other immunosuppressive agents. These drug combinations have the advantage of exploiting additive and synergistic drug effects while concomitantly minimizing the adverse reactions.

From the very beginning the steroid-sparing potential of CsA has been a main consideration in all clinical situations. In transplantation a state of true tolerance has not been achieved (with the exception of bone marrow transplants) and, therefore, as with other immunosuppressants, lifelong therapy is necessary. Although acute rejection can now be effectively controlled, there remains, in the long-term, the problem of chronic rejection which is considered as one of the leading causes of late allograft failure.

The kidney is the most frequently transplanted organ. Before the CsA era the overall one-year graft survival rate was about 60%, depending on the center. Since the introduction of CsA it has now risen to 80–90%. In kidney recipients followed for up to 10 years renal function tended to worsen during the first year, but remained stable thereafter with no progressive renal damage. The use of CsA in liver transplantation had the effect of revitalizing the field and

soon this procedure was accepted as a treatment option for end-stage liver disease and no longer considered experimental. The 5-year survival of patients, which was about 20% before the use of CsA, increased to 60%. With CsA the number of heart transplantations increased rapidly and currently a 5-year survival rate of approximately 70% is obtained. Heart-lung and lung transplantation was never successful without CsA. The one-year survival of the former has been about 60–65% with CsA. Transplantation of the pancreas simultaneously with a kidney offers a successful treatment for patients with type I diabetes mellitus and end-stage renal failure. A one-year graft survival of about 80% can be achieved at the best centers. In bone marrow transplantation the use of CsA has resulted in a reduction in the severity of graft-versus-host disease. Its use is also associated with prompt and sustained engraftment, quicker hematological recovery and a shorter hospital stay.

CsA in autoimmunity

Since 1987 CsA has also been registered for the treatment of several autoimmune disorders. The use of CsA in this field was based on a solid pharmacological rationale and was also a logical consequence of its superior efficacy in organ transplantation. By their very nature the autoimmune diseases demand a different evaluation of the risk-benefit ratio inherent in all forms of therapy. Indications subjected to investigation were selected on the basis of the experimental results in animal models of autoimmunity and on the medical need. The efficacy of CsA has been proven in several such diseases with clinical benefit being demonstrated in some and remaining uncertain in others as shown in Table 1.

CsA is efficacious in many autoimmune diseases, both for induction and maintenance of remission. Common features of the clinical effects of CsA are relatively quick onset of effect and also the occurrence of relapses when treatment is stopped. The autoimmune reaction seems temporarily 'frozen', without correction of the intrinsic autoimmune defect. Nevertheless, it is evident that many patients who do not respond satisfactorily to conventional therapy, in terms of efficacy or toxicity, may profit from CsA. However, in therapy-resistant end-stage patients who present with substantial pathology which is irreversible, the full potential cannot be realized. The use of the drug may thus eventually be extended to less advanced disease stages.

Uveitis (autoimmune, Behçet disease)
 Psoriasis
 Idiopathic nephrotic syndrome
 Rheumatoid arthritis

Unclear benefit

Severe aplastic anemia
 Crohn disease
 Atopic dermatitis
 Asthma
 Primary biliary cirrhosis
 Myasthenia gravis
 Insulin-dependent diabetes mellitus

Efficacy suggested by uncontrolled studies

Systemic lupus erythematosus
 Dermatomyositis/polymyositis
 Ulcerative colitis
 Pyoderma gangrenosum
 Membranous nephropathy and other autoimmune glomerulonephritides

Efficacy questionable

Multiple sclerosis
 Endocrine ophthalmopathy
 Sjögren syndrome
 Sarcoidosis
 Pemphigus
 Polychondritis

Adverse events

One of the most important issues is safety on long-term treatment. The adverse events recorded are similar in all indications. Apart from the general risks of immunosuppression (opportunistic infection, malignancy) the most important side-effects of CsA are nephrotoxicity and hypertension. Others include anorexia, nausea, vomiting, paresthesia, hypertrichosis, gingival hyperplasia and tremor.

Although infections do occur with CsA, they appear to be more amenable to treatment. The occurrence of lymphomas or lymphoproliferative disorders is now recognized to be the result of over-immunosuppression. Experience gained so far indicates that the incidence of cancers following the use of CsA is no higher than with other types of immunosuppressive therapy. Today the nephrotoxicity of CsA is considered to be manageable. This is achieved, in transplantation, by dosage adjustments based on the monitoring of CsA blood concentrations. Added to that is the increased understanding of the nephrological findings in kidney biopsies

from patients exposed to the drug. In autoimmune diseases CsA is kept at the lowest effective dose, i.e. exceeding $5 \text{ mg kg}^{-1} \text{ day}^{-1}$, and this is decreased whenever serum creatinine increases by more than 30% over the individual baseline value. In addition, regular monitoring of blood pressure is recommended. Hypertension, if it occurs, is responsive to the standard therapy. One must also be aware of pharmacokinetic interactions which may result in either an increase (e.g. ketoconazole) or decrease (phenytoin) of the CsA blood concentration.

CYSTICERCOSIS

Donald P McManus, Molecular Parasitology Unit, Tropical Health Program, Australian Centre for International and Tropical Health and Nutrition, The Queensland Institute of Medical Research, Brisbane, Queensland, Australia

Characteristics of the organisms and their antigens

The term 'cysticercosis' is a general one applied to the occurrence of cystic (larval) stages of cestodes (tapeworm parasites) in humans and domestic and laboratory animals. Cysticercosis due to the cysticercus (known by veterinarians as *Cysticercus cellulosae*) of the pig tapeworm, *Taenia solium*, is the most common simple cystic form in humans. The life cycle of *T. solium* is depicted in Figure 1. Pigs act as the intermediate host and the adult worms occur in the human gut. In pigs the cysticercus may lodge anywhere in the body but shows predilection for muscle. When undercooked or raw pork infected with cysticerci (measly pork) is eaten by humans, the scolex (activated by bile) evaginates and becomes attached to the duodenum, the bladder of the cysticercus is digested and the worm differentiates into an adult. The fully developed adult (up to several meters long) sheds single segments or proglottids (proglottis = single segment) each containing 50 000 eggs and these are voided in the feces. On ingestion by a pig, the egg hatches in the gut to release the oncosphere which bores its way through the mucosa and into the general circulation, finally localizing and developing in body muscle.

Neurocysticercosis

The eggs of *T. solium*, when ingested by humans, can also develop into cysticerci. Their presence causes a serious and often fatal disease due to the frequent involvement of the nervous system (neurocysticercosis), resulting in 'cysticercus epilepsy'. *T. solium* occurs in most pork-eating countries where sanitary conditions are primitive and scavenging pigs have access to human fecal material. Neurocysticercosis is now the most prevalent disease of the central nervous system in the USA, although most of the patients appear to have originated from Mexico or Latin America. The disease is also a major health hazard, and has been reported from Africa, China, Japan, Indonesia, Poland, Italy, Spain and Central and South America but has virtually disappeared from most other areas of Europe.

Other cysticercoses

Other important cysticercoses are caused by *T. saginata* in cattle (adult in humans), *T. ovis*, *T. hydatigena* and *T. multiceps* in sheep (adults in dogs). Another human *Taenia* has recently been identified in South-East Asia; new genetic evidence and earlier biological studies suggest this 'Asian *Taenia*' is a distinct entity, but that it is closely related to, and should best be regarded taxonomically as, a subspecies or strain of *T. saginata*. Valuable experimental models for immunologic studies of cysticercosis include *T. taeniaeformis* in rats, *T. crassiceps* in mice and *T. pisiformis* in rabbits. This group of worms collectively belong to the family Taeniidae (the taeniids) but the account given here has especial emphasis on *T. solium* because of its medical importance. Hydatid disease, caused by dog tapeworms of the genus *Echinococcus* is, strictly speaking, also a cysticercosis.

Antigens

Few antigens have been characterized from tapeworms and much work has been aimed at providing reagents suitable for specific and sensitive immunodiagnosis. Antigen B (95–105 kDa) (paramyosin, see below), an immunodominant antigen of *T. solium*, believed previously to be specific, has now been shown to cross-react with antibodies produced to a number of other human helminth infections. Two low molecular weight antigens (26 kDa and 8 kDa) have been identified as specific for *T. solium* and appear to provide requisite diagnostic sensitivity. Most encouragingly, seven major lentil lectin-binding glycoprotein antigens (13–50 kDa) have been identified in *T. solium* and these have been applied very successfully in a highly specific and sensitive western blot assay for diagnosing human cysticercosis, and for immunodetection of infected pigs. ELISA tests have also been developed for detection of *Taenia* antigens in the feces of human carriers. Some protective antigens have been partially characterized and these include molecules from *T. taeniaeformis*, *T. saginata* and *T. ovis* (see below). Very few of these antigens have been localized and further work in this area is clearly warranted.

Figure 1 Life cycle of the 'pork' tapeworm, *Taenia solium*. Note that the larval stage (cysticercus) can develop in humans, causing the dangerous and often fatal disease neurocysticercosis. (After Smyth (1994), with permission.)

Immune response of the host

T. solium, similar to other larval cestodes in mammals makes intimate contact with host tissue at two sites (Figure 2): 1) during the early phase of infection, when the recently hatched oncosphere penetrates the intestine; and 2) at the final encystment site, commonly in muscles, viscera and the nervous system. The immune response at the oncosphere penetration site is often referred to as 'early' or 'pre-encystment' immunity, and that at the final establishment site as 'late', 'postoncospherical', or 'postencystment' immunity (Figure 2).

Secretory immunoglobulin A (IgA) in gut secretions and (where relevant) in colostrum prob-

ably plays an important role in attacking invading oncospheres, a situation related to the fact that this antibody may be resistant to intestinal enzymes. Thus infection of mice with *T. taeniaeformis* results in the production of intestinal IgG antibodies protective against challenge infection, and oral immunization results in a protective immune response against this species. An IgA antibody response has also been reported following *T. taeniaeformis* infection in rats and *T. pisiformis* infection in rabbits.

Mast cells accumulate around both invading oncospheres and developing larvae and it is possible that IgE may react with antigen, causing degranulation of these cells with a consequent increase in vascular permeability; this would allow IgG anti-

Figure 2 Pattern of immune responses on an oncosphere of a taeniid cestode such as *Taenia solium* during initial penetration of the hatched oncosphere (initiating 'early immunity') and its subsequent migration to, and establishment in, its definitive site, where it is subject to 'late immunity'. The exact site of hatching in humans is unknown but most eggs probably hatch in the upper duodenum. (After Smyth and McManus (1989), with permission.)

bodies to more easily reach the invading site. Eosinophils may accumulate around invading oncospheres, but there is no evidence that these cells actually damage oncospheres or postoncospherical stages. The role of macrophages or neutrophils, which may accumulate at the site of dying oncospheres, remains unknown.

When newly hatched oncospheres reach their site of establishment, they become transformed from a stage of being highly susceptible to attack to one of almost complete insusceptibility. The cellular and humoral response in *T. solium* cysticercosis is heterogeneous in humans and pigs. IgG represents almost 90% of the serum antibody detectable by ELISA but some patients show no antibody or cellular response whatsoever. Cysticerci of *T. solium* elicit a chronic granulomatous reaction in pig muscle. There is extensive eosinophil infiltration and degranulation on to the parasite surface but no apparent damage ensues. As in *T. solium*, eosinophilic response to *T. taeniaeformis* is antibody dependent. Eosinophils have been shown to adhere to and damage *T. taeniaeformis* *in vitro* but it is not clear if this occurs *in vivo*.

Little is known of T cell immunity to larval cestodes, although CD4⁺ T helper cells have been implicated in the early phase of resistance to infection with *T. taeniaeformis* in mice. Such cells may be activated by parasite to produce cytokines involved in

maturation and activation of eosinophils. Alternatively they may mediate interaction between hepatocytes and the parasite, thereby causing an alteration in the lipid metabolism of the former, resulting in the production of an eosinophilic chemotactic factor. Much work remains to be done in this important area.

Evasive strategies

The ability of tissue parasites, such as the larval taeniids, to survive in an immunologically hostile environment represents a phenomenon of special interest and controversy.

Blocking antibodies

In larval cestodes, host proteins have been demonstrated on the surface, including antibodies, these being referred to as 'blocking' antibodies. Thus, on the surface of the cysticerci of *T. solium*, a number of immunoglobulin isotypes have been found. In the case of *T. crassiceps* larvae, the predominating immunoglobulins appear to be IgM and IgG but, with this species, complete protection against immune attack may not be provided.

Molecular mimicry

The theory of molecular mimicry proposes that

parasites disguise themselves as host (i.e. self) tissues by synthesizing host-like antigens on their surface, with the result that they are not recognized as foreign (i.e. nonself) by the host. There has been much controversy as to whether larval cestodes are capable of synthesizing such antigens or whether they have simply been absorbed from the host. Some evidence suggests that parasites can synthesize receptors or binding proteins capable of associating with host molecules. For example, an IgG (Fc γ)-binding protein has been identified and purified from *T. crassiceps*.

There is evidence that the fact that the postoncospherical stages rapidly outgrow their susceptibility to attack may be due to development of stage-specific antigens related to profound alterations in the surface structure of the developing larva. Thus, a strong immune response is generated against *T. taeniaeformis* in the liver, and larvae become insusceptible by 8 days – a time that coincides with the surface replacement of microvilli by microtriches.

Secretory products

Some larvae (e.g. *T. pisiformis*, *T. taeniaeformis*) release substances which inhibit proteolytic enzymes such as trypsin and chymotrypsin. Taeniaestatin, a 19.5 kDa secretory protein from *T. taeniaeformis*, in addition to inhibiting these enzymes, also inhibits neutrophil chemotaxis, the alternative and classical complement pathways, and interleukin 2 stimulation of T-cell proliferation. Antigen B (AgB) of *T. solium*, a secretory protein which has the ability to bind collagen, can inhibit, *in vitro*, the classical pathway of complement through inhibition of C1 function and may play a role as a modulator of the host immune response in cysticercosis. Interestingly, AgB has immunologic and sequence homology with the invertebrate muscle protein paramyosin. Whether secretory products of other species can potentially modify the host cellular responses in a similar fashion remains to be established.

Immunosuppression

There are several reports that some cestode larvae can induce immunosuppression in their hosts. For example, the sera of rabbits heavily infected with *T. pisiformis* have an inhibitory effect on the lectin-mediated blast transformation of lymphocytes. Furthermore, polyclonal B cell activation has been suggested as an immunosuppressive mechanism in human *T. solium* infections, while mice infected with *T. crassiceps* have impaired ability to make antibodies against sheep red blood cells.

Vaccines

The development of successful vaccines against the highly pathogenic larvae of *T. solium* (in humans and pigs) and those of economic importance, such as *T. saginata* (in cattle) and *T. ovis* and *T. multiceps* (in sheep) would clearly revolutionize the control of these important parasites. Studies with *T. saginata*, *T. ovis* and other taeniid species have shown that vaccination with living eggs, the parasite-free supernatant from *in vitro* culture of hatched and activated oncospheres, or detergent solubilized oncospherical antigens can induce complete protection against challenge infection. A major difficulty has been the limited supply of eggs, which has prevented the development of a practical vaccine.

Recently, recombinant DNA techniques have been applied to the problem of large-scale production of taeniid vaccine antigens, and the expression in *Escherichia coli* of cDNAs encoding taeniid antigens has been achieved. In particular, a highly effective recombinant antigen vaccine against *T. ovis* has been developed. Vaccination of sheep with this molecule, expressed as a soluble glutathione *S*-transferase fusion protein (GST-45W), stimulated 94% protection against challenge infection with *T. ovis*. Initial trials with the 45W clone as a β -galactosidase fusion protein proved unsuccessful. The antigen was stabilized subsequently by modification of the original

Table 1 Results of a pilot field trial showing numbers of *Taenia ovis* cysts found in the carcasses of vaccinated lambs naturally (field) or artificially infected with *T. ovis* eggs

Group	Number	Range of cysts	Mean	Protection (%) [*]
Controls – field infection	12	36–348	92	—
Controls – artificial challenge	10	74–254	156	—
Vaccinated – field infection	12	0–11	1.8	98
Vaccinated – artificial challenge	18	0–203	11.7	92

^{*}Expressed as percentage reduction of infection compared with respective controls. Modified from Rickard *et al* (1995).

cDNA; the modified antigen (GST-45B/X) was also highly effective in vaccinating sheep. Field trials with *T. ovis* recombinant antigen GST-45B/X (Table 1), in conjunction with saponin, the most effective adjuvant, again provided encouragingly strong protection against infection and this formulation is currently commercially registered. GST-45B/X does not cross-protect against *T. hydatigena*, *Echinococcus granulosus* or *Taenia saginata* and maternal antibody has been shown to interfere with development of immunity in vaccinated lambs. Other potentially protective, cloned *T. ovis* antigens (GST-16 and GST-18) have been identified, and it is likely that similar recombinant products could be developed against *T. solium* and *T. saginata*. Indeed, some cloned *T. saginata* and *E. granulosus* antigens are already under trial; with the latter, more than 95% protection has already been obtained in two separate trials with sheep.

CYTOKINE ASSAYS

Fionula M Brennan, Charing Cross Sunley Research Centre, Hammersmith, London, UK

Catherine Haworth, Department of Haematology, Leicester Royal Infirmary, Leicester, UK

Cytokines may be assayed by biological properties, immunological recognition (ELISA or radioimmunoassay), competitive binding to the receptor molecule and by inference from the transcription of the mRNA. The advantages and disadvantages of each technique are summarized in Table 1. In general, bioassays are very sensitive and by implication verify biological activity of the cytokine; they are not however always very reproducible or specific. In contrast immunoassays, although reproducible and specific, are not nearly as sensitive as bioassays, although more recently the sensitivity of immunoassays has improved with the use of amplification techniques.

Immunoassays

Immunoassays detect cytokines using a combination of polyclonal and monoclonal antibodies directed against the cytokine or two different complementary monoclonals. In either case the antibodies should be raised against purified cytokines, preferably recombinant products or peptide derivatives to ensure specificity. There are essentially two main types of immunoassay; the enzyme-linked immunoabsorbent assay (ELISA) and the immunoradiometric assay (IRMA). In both cases the cytokine is detected by antibody capture.

In the ELISA the first antibody (polyclonal or

Table 1 Comparison of methods of cytokine detection

	<i>Evidence of bioactive protein</i>	<i>Sensitivity</i>	<i>Technical skill</i>	<i>Specificity</i>	<i>Effect of inhibitors</i>

Bioassay	+	++	Variable	±	+
mRNA	—	Variable depending on technique	++	++	

monoclonal) is coated to plastic, followed by incubation with the sample or cytokine standard. The cytokine is then detected using the second antibody (monoclonal) conjugated to an enzyme and visualized using the appropriate substrate (Figure 1). Further layers on this sandwich technique can be applied to increase the sensitivity. For example unconjugated second monoclonal is detected using an anti-mouse immunoglobulin G (IgG) enzyme conjugate followed by the substrate. Alternatively the second monoclonal is conjugated with biotin followed by streptavidin enzyme complex.

**Figure 1** The enzyme-linked immunosorbent assay (ELISA).

The IRMA technique is also based on antibody capture as in the ELISA but the detection system depends on ^{125}I -labeled antibodies. In this case the first antibody is coated to a bead, followed by incubation with the cytokine in the fluid phase which is detected by iodinated cytokine-specific antibody (Figure 2).

In either system the relevant dilution of the different components in the assay require to be determined first and then the detection limits of the immunoassay established. This part is time consuming but ensures that the assay is reproducible and that the assay is as sensitive as possible. The limits of detection for such capture assays are normally around 30–50 pg ml⁻¹ with the upper range at approximately 10 000 pg

**Figure 2** The immunoradiometric assay (IRMA).

ml⁻¹. The detection limit depends upon a number of factors including the affinity of the relevant polyclonal and/or monoclonal antibodies used, in addition to the sample diluent which may contain inhibitory binding proteins. The use of high-affinity monoclonal antibodies and amplification systems has increased the sensitivity of many cytokine ELISAs to 10 pg ml⁻¹.

Advantages and disadvantages

The advantage of the ELISA method over the IRMA is that the reagents have a longer shelf-life as their detection system does not depend on radiolabeled antibodies. However, as the ELISA is a solid-phase assay the detection limit is not as good as the fluid-phase IRMA (presumably due to steric hindrance). In both cases the assays only measure antibody binding to the cytokine and not necessarily biological activity. This is an important fact to consider as inhibitors in the sample or bound to the cytokine itself may not interfere with immunobinding but render it biologically inactive. Furthermore it is important (as in any assay) to use the appropriate standards. Many native cytokines are glycosylated (e.g. interferon γ) which may have different biological and immunobinding properties to nonglycosylated recombinant products. Thus it is important to measure cytokines in immunoassays using a standard (e.g. glycosylated recombinant cytokine) which reflects the cytokine in the sample.

Standard preparations

In both immunoassays and bioassays (discussed in the next section) it is important to use reference or standard preparations of the cytokine both to establish the assay and further to allow interassay comparison. Cytokines are defined both in terms of protein concentration (pg ml⁻¹) and specific activity (units mg⁻¹). A unit is defined as that amount of cytokine which gives 50% maximal activity in the bioassay. As certain cytokines can be measured by more than one bioassay (which can vary up to tenfold in sensitivity) this measurement is purely arbitrary depending on the bioassay used. In conclusion, in both immunoassays and bioassays the standard preparation (recombinant material) should be used to standardize the technique and the results expressed both as protein concentration and units mg⁻¹.

Bioassays

Bioassays (Table 2) are necessary to establish that the system under investigation is producing active protein and the design must take the following into account:

- Cytokines have overlapping bioactivity and there-

fore the assay must be designed to eliminate contributions from other cytokines.

- Specific inhibitors may be produced in the same experimental systems that produce the active cytokines e.g. interleukin 1 inhibitor.
- Nonspecific inhibitors may exist in the system, e.g. α_2 -macroglobulin or enzymes which degrade cytokines, e.g. encephalinase.

Further it is advantageous if the system:

- uses a target system which is easily available;
- has clear endpoints;
- requires only small amounts of test material.

Cytokine bioassays will be discussed with reference to the following:

- choice of target system
- choice of property to be assayed
- ensuring specificity
- inhibitor proteins.

Target cells

The choice usually lies between purified and nonpurified populations of normal cells versus cell lines. The latter have the advantage that if the appropriate cell line exists it can be available in large amounts, with comparable sensitivity between experiments (though drifting of sensitivity of cell lines may take place), and secondary effects from accessory cell populations are eliminated. However, when no cell lines exist or when new activities are being sought in physiological circumstances normal cells may be more useful. It is often necessary to enrich the target cell population to ensure that the assay is sensitive and linear over an adequate range. Enrichment may be done *in vivo*, e.g. the assay for mouse IL-5 (Eo-CSF) activity done on bone marrow cells enriched for eosinophil precursors by infecting the animal with *Mesocostoides corti*. When it is necessary to completely eliminate accessory cell effects target cells must be rigorously separated from contaminating cells, e.g. by FACS sorting. Cytokines have a wide variety of patterns of interspecies cross-reactivity viz:

- cytokines that are species nonspecific, e.g. TGF β s;
- human cytokines acting in human systems only, e.g. interferon γ ;
- human cytokines acting in mouse systems (but not vice versa), e.g. hematopoietic growth factors, IL-1, IL-2, IL-4, IL-6. Thus some human cytokines can be tested against mouse cells.

Properties

The choice of property of the cytokine to be tested will be influenced mainly by the ease and sensitivity

Table 2 Bioassays used to detect cytokine activity

<i>Cytokine</i>	<i>Target cell</i>	<i>Read-out</i>	<i>Important contaminating cytokines</i>
IL-1	D.10 (mouse T cell)	[³ H]thymidine incorporation	IL-2 (human and mouse), IL-4, GM-CSF, IL-7, TNF (mouse only). IL-6
	Mouse thymocyte	[³ H]thymidine incorporation	IL-2 (human and mouse), IL-4, IL-7 (mouse), IL-6. Inhibited by interferon γ (mouse), TGF β 1, TGF β 2, TNF (mouse).
	EL.4	IL-2 induction read in CTLL assay	IL-4 and IL-2 carry over to CTLL assay
IL-2	CTLL	[³ H]thymidine incorporation	IL-4 (mouse) TGF β 1, TGF β 2 inhibit at low IL-2 levels
IL-3	Hematopoietic cell lines e.g. FDCP.1 (mouse) Mo7E (human)	[³ H]thymidine incorporation	GM-CSF
	Bone marrow	20 α steroid dehydrogenase	
	Hematopoietic colony assays in semi-solid agar	Colony numbers	
IL-4	B cells (mouse only)	CD23 induction HLA class II	Inhibited by interferon γ
	Co-mitogenesis with PHA-stimulated mouse T cells	[³ H]thymidine incorporation	
	IL-4-dependent T cell lines	[³ H]thymidine incorporation	
IL-5	Induction of eosinophil maturation from bone marrow in semi-solid or liquid culture (human and mouse)	Microscopy	IL-3
	Normal mouse B cells treated with anti-immunoglobulin	IgM secretion	
	BCL-1	[³ H]thymidine incorporation	
IL-6	B9 mouse hybridoma (sensitive to human, and mouse IL-6)	[³ H]thymidine incorporation	IL-4 (mouse), IL-11
	Hepatocytes (Hep G 2)	Fibrinogen production	
	CESS cells (EBV transformed human B cells)	IgG production	
	SKW cells	IgM production	
IL-7	Bone marrow pre-B cells from Whitlock–Witte cultures	[³ H]thymidine incorporation	
IL-8	Neutrophils	Chemotaxis	Other neutrophil chemotactic factors including G-CSF, M-CSF
IL-10	MC9 mouse mast cell line Sensitive to mouse and human IL-10	[³ H]thymidine incorporation	IL-3
IL-11	B9 mouse hybridoma or B9/11 (subclone with higher sensitivity)	[³ H] thymidine incorporation	IL-6
IL-12	PHA-activated lymphoblasts	[³ H] thymidine incorporation	IL-2
IL-13	Human B cells costimulated with CD40 antibody	[³ H] thymidine incorporation	IL-4
IL-15	Activated T cells	[³ H] thymidine incorporation	IL-2, IL-12
TGF β ₂	NRK cells	Anchorage-independent growth	TGF α
Activin/inhibin	Cultured pituitary cells	FSH release $\uparrow/\downarrow$	
GM-CSF	Normal bone marrow progenitor cells	Granulocyte macrophage colonies	IL-3, inhibited by TGF β , TNF
	GM-CSF-dependent cell lines (see IL-3 above)	[³ H]thymidine incorporation	
G-CSF	Normal bone marrow progenitors Neutrophils	Granulocyte colonies Activation, e.g. superoxide release	GM-CSF GM-CSF, IL-6
TNF/LT	WEH1 164 clone 13 L929	Cell viability – by MTT cleavage by mitochondria and OD reading	

Table 2 Continued

<i>Cytokine</i>	<i>Target cell</i>	<i>Read-out</i>	<i>Important contaminating cytokines</i>
PDGF	Fibroblasts, e.g. cell lines SS, WHG, WI26 or 28	Proliferation	FGF (1, 2, 5), EGF, TGF β , IL-1, TNF, amphiregulin, oncostatin, Kaposi growth factor
IFN γ	Many, e.g. human diploid fibroblasts	Resistance to viral cytopathic effect, e.g. VSV	IFN α and β
IFN α /IFN β	DAUDI human lymphoblastoid B cell line	Inhibition of cell growth [3 H]thymidine incorporation	TGF β
MIF	Macrophages	Inhibition of migration in agar	IL-4/IFN γ
VEGF	Endothelial cells	[3 H]thymidine incorporation	
<i>C-C chemokines</i>			
I-309	Monocytes	Chemotaxis	Other monocyte chemoattractants
MCP-1/2/3	Monocytes or basophils	Chemotaxis	Other monocyte chemoattractants
MIP-1 α	Eosinophils or inhibition of CFU-A	Chemotaxis [3 H]thymidine incorporation	
MIP-1 β	Memory T cells	Chemotaxis	RANTES
RANTES	Memory T cells eosinophils	Chemotaxis	MIP-1 β and others
<i>C-X-C chemokines</i>			
γ IP10	Monocytes	Chemotaxis	Other monocyte chemoattractants
MIP-2	Neutrophils	Chemotaxis	Other PMN chemoattractants
CTAP-III	Neutrophils, fibroblasts	Chemotaxis	Other chemoattractants

of the read-out assay, the extent to which other cytokine activities overlap and the ease with which their contribution can be eliminated. In general the multiple functions of individual cytokines are associated with the same epitope and therefore properties of individual molecules do not vary with respect to each other, e.g. the collagenase activity of IL-1 is parallel to its T cell activity. The properties which are usable in assays may be divided into two groups: (stimulation and inhibition of) proliferation and function. The former may be assayed by growth stimulation (usually [3 H]thymidine incorporation) into sensitive cells or by assaying mitochondrial function as an indicator of cell viability, e.g. by cleaving 3-(4,5-dimethylthiazol-2yl)-2,5-diphenyltetrazolium bromide (MTT) to form a dark blue formazan product. Such assays have the advantage of similarity of technique for a variety of cytokines and therefore many can be assayed with semiautomated equipment.

Functional assays are much more heterogeneous. They are necessary when the cytokine to be tested has no growth related properties (e.g. IL-8 must be assayed in neutrophil migration assays), or where the functional properties are more specific than the growth-related properties. Some cytokines can only be specifically bioassayed in organ culture (e.g. Mullerian inhibitory substance by assaying regression of 14-day fetal rat embryo urinogenital tracts) or *in vivo* (e.g. EGF-induced eyelid opening in neonatal

mice or MIP1- and 2-induced neutrophil chemotaxis in mouse cerebrospinal fluid).

Specificity

It has already been stated that many biological effects are mediated by more than one cytokine, e.g. bone resorption is induced both by IL-1 and TNF α and many cells respond to more than one cytokine as a growth factor, e.g. mouse thymocytes respond to IL-1, IL-4, IL-6 and IL-7 to varying degrees, in addition the test preparations may contain both stimulatory and inhibitory cytokines, e.g. TGF β is inhibitory in many of the IL-1 assays and assays where early hematopoietic cells are the target, and interferon γ inhibits many IL-4 assays.

Specificity may be increased by a variety of techniques:

1. Selection of assay systems where two cytokines with overlapping properties are likely to coexist, nonoverlapping properties may be selected for assay, e.g. human GM-CSF and G-CSF may be distinguished as the former has growth stimulatory properties on the megakaryoblastic leukemia cell line Mo7E.
2. The cells may not have linear responses to the different cytokines at the same dilutions of the test material, therefore the assay conditions can be arranged to favor the cytokine under test.
3. Use of mouse target cells may reduce the range

of human cytokines influencing the assay (see above).

4. When known cytokines are likely to influence the assay addition of excess neutralizing antibodies (plus appropriate control antibodies for monoclonal antibodies or serum for polyclonal antibodies) may be used to enhance specificity.
5. To further ensure that the activity assayed is attributed to the correct cytokine, neutralizing antibodies to the cytokine must completely abrogate all bioactivity.

Inhibitor proteins

Specific physiological inhibitors of, for example, IL-1 and TNF of the relevant cytokine influence bioassays.

Radio-receptor binding assays

Cytokines may also be assayed by competitive binding for the receptor between the test material and radiolabeled (usually ^{125}I) ligand. This assay requires availability of cells expressing high levels of the receptor and that optimal conditions of ligand and receptor binding are understood. In addition, non-specific interference in receptor ligand binding must be excluded by including controls for the media and buffers in the materials to be tested.

The assay involves incubation of iodinated ligand with varying dilutions of test or standard material under optimal conditions which must be predetermined for each receptor ligand pair, possibly at 4° to reduce internalization. This is followed by wash-

ing to remove excess ligand, solubilization of the ligand receptor complexes and counting in a γ -counter.

Problems intrinsic to this assay are:

- cytokines and their receptors may exist in several forms, e.g. PDGF and PDGF receptor with different binding coefficients;
- cytokines can cross-compete for the same receptor, e.g. IGF1 and IGF2, and MGSF (melanocyte growth-stimulating factor) and IL-8;
- cytokine inhibitors may bind to the cytokine receptor with equal avidity to the cytokine.

CYTOKINE GENES, REGULATION OF

David R Fitzpatrick, Mark Egerton and Anne Kelso, Transplantation Biology Unit, Queensland Institute of Medical Research, Brisbane, Queensland, Australia

Cytokines play a central role in the immune response by promoting the activation of antigen-specific and nonspecific effector mechanisms and tissue repair. Selective cytokine production in particular can determine the outcome of a response by stimulating protective or exacerbative immune mechanisms. On the other hand, cytokines can be pathogenic when produced in excess, by causing overproduction of inflammatory cells, fever, vascular leakage, tissue damage and lethal shock. Multiple levels of cytokine gene regulation therefore exist to ensure that, in most circumstances, cytokine synthesis is limited in time and space.

Cell lineage-specific cytokine synthesis

Most, if not all, nucleated cell types can synthesize cytokines but different cell lineages vary in the combinations they produce. T lymphocytes collectively produce many of the known cytokines of immunologic interest, including most of the interleukins, interferon α (IFN α), β and γ , granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor α (TNF α) and β , lymphotoxin α , lymphotoxin β and transforming growth factor β (TGF β); they apparently do not produce IL-7, IL-11,

IL-12, IL-14, IL-15, G-CSF or M-CSF. Different but overlapping sets of cytokines are produced by other cell lineages, including B lymphocytes, dendritic cells, monocytes and macrophages, natural killer (NK) cells, mast cells, neutrophils, eosinophils, megakaryocytes, fibroblasts, endothelial and epithelial cells. Whereas expression of some cytokines (notably IL-1, IL-6, GM-CSF and TNF α) is widely distributed among lineages and tissue types, others are highly restricted. For example, IL-2 and IL-4 production appears limited to T cells and mast cells and IL-12 production has only been reported in B cells, dendritic cells and macrophages. Further heterogeneity is seen within cell lineages. While individual T cells can simultaneously express multiple cytokine genes, different CD4⁺ and CD8⁺ T cells can synthesize many different cytokine combinations. Two extreme T cell cytokine profiles are the type 1 and type 2 patterns, distinguished by their mutually exclusive expression of IL-2, IFN γ and TNF β in the former case and IL-4, IL-5, IL-6, IL-9, IL-10 and IL-13 in the latter case.

Inducibility of cytokine synthesis

Production of most cytokines does not occur constitutively but depends on appropriate stimulation of the producer cell. For example, naive peripheral T cells do not synthesize detectable levels of any known cytokines but acquire this function as a result of combined stimulation through the T cell receptor for antigen (TCR) and receptors for costimulatory signals, such as CD80 or CD86 acting through CD28 on the T cell. Once activated, subsequent bursts of cytokine synthesis can be induced through the TCR or certain other receptors alone. Induction of cytokine synthesis is also antigen dependent in some other cell types, such as NK cells, mast cells and eosinophils, which can be triggered by binding of antigen-antibody complexes to Fc receptors. Other physiologically important ligands that can stimulate cytokine synthesis include bacterial lipopolysaccharide, extracellular matrix and cytokines themselves; the last can in some cases stimulate their own synthesis or initiate a cascade of synthesis of other cytokines.

Both coordinate and differential cytokine production can be observed in a single cell type. In previously activated T cells, for example, TCR cross-linking induces a transient wave of mRNA and protein synthesis for multiple cytokines with comparable kinetics. Costimulatory signals and cytokines can modulate this TCR-dependent cytokine synthesis

and, in some cases, can also differentially stimulate the TCR-independent expression of certain cytokines. Conversely, some physiologic regulators (such as glucocorticoid hormones) and therapeutic agents (such as cyclosporine) can inhibit cytokine synthesis in a coordinate or selective manner. Patterns of cytokine synthesis therefore depend not only on the lineage and activation status of the producer cell, but also on the combination of signals it receives.

Signal transduction

The signal transduction pathways that couple surface receptor stimulation to inducible cytokine gene expression have been most extensively studied in T cells. The common theme that has emerged is that a variety of distinct pathways converge at the level of transcription factor regulation to control cytokine gene transcription. Pathways that might regulate post-transcriptional events are much less well defined.

Three major signaling pathways activated by TCR ligation regulate cytokine production in T cells. These pathways and the transcription factors through which they act are as follows: 1) a calcium-dependent pathway regulating NFAT family members; 2) a protein kinase C (PKC)-dependent pathway that acts through AP-1 and NF- κ B; 3) pathways activated by p21^{ras} that work primarily through AP-1. The calcium-dependent and PKC pathways share a common activator, phospholipase-C- γ -1. Tyrosine phosphorylation activates phospholipase C- γ -1 resulting in the hydrolysis of phosphatidylinositol 4,5-bisphosphate to inositol triphosphate and diacylglycerol. The released inositol triphosphates stimulate the release of calcium ions from intracellular stores, activating the calcium-calmodulin dependent serine/threonine phosphatase calcineurin, which dephosphorylates NFAT proteins, resulting in their translocation to the nucleus. The importance of this pathway is evidenced by the presence of NFAT consensus binding sites in the regulatory regions of all cytokine genes studied, and the devastating effect of the calcineurin inhibitor cyclosporin A upon cytokine production. Diacylglycerol activates PKC- α and - ϵ isoforms, which activate cytokine gene expression via the NF- κ B and AP-1 transcription factors. NF- κ B activation is achieved by phosphorylation of the inhibitory subunit I κ B, which promotes dissociation of I κ B from the inactive cytosolic complex and allows the nuclear translocation of NF- κ B. AP-1 regulation is achieved through activation of the MAP kinases, which are downstream effectors of both PKC and p21^{ras}.

Stimuli that affect T cell commitment to the production of particular cytokines, such as IL-12 for the promotion of type 1 responses and IL-4 for the promotion of type 2 responses, utilize a set of signaling molecules distinct from those activated by the TCR. These include members of the JAK family of tyrosine kinases and their substrates, the STAT transcription factors. There is evidence that the establishment of stable cytokine production phenotypes is associated with modulation of these signaling pathways.

Transcriptional activation

Expression of most of the known cytokines is regulated primarily at the levels of *de novo* transcription and mRNA turnover. Multiple DNA-binding proteins have been identified as important regulators of cytokine transcription. Cytokine enhancer and promoter elements usually contain several transcription factor binding sites, sometimes with multiple sites for each factor, and the interplay between individual transcription factors, and complexes containing these factors, is an important feature of cytokine gene regulation. Many of these transcription factors regulate multiple cytokine genes in a variety of cell types, and specificity is thought to be achieved through the formation of specific transcription factor combinations acting through specific cytokine gene regulatory elements.

The activity and composition of these complexes can be regulated by five distinct means. The first is transcription factor accessibility. DNAase I hypersensitive sites reflect chromatin accessibility, are associated with active transcription and can vary between cell types in accordance with lineage-restricted cytokine production. Transcription factor access may also require demethylation of genomic DNA bearing 5-methylcytosine at CpG dinucleotide sequences. The initiation of enhancer- and promoter-driven transcription in a cytokine gene may be preceded by release from the influence of specific silencer elements. Second, transcription factor activity is affected by the DNA sequences with which the complexes interact, an example being the preference of the composite NFAT/AP-1 binding site in the IL-4 promoter for AP-1 components other than *c-fos* and *c-jun*. Polymorphisms in regulatory sequence elements of the human IL-1 β and IL-4 genes have been shown to be associated with variations in transcriptional activity between individuals. The third level of control is the availability of transcription factors in the nucleus, for example NFAT and NF- κ B family members, whose translocation to the nucleus requires dephosphorylation and phosphorylation/proteolysis-dependent mechanisms respect-

ively. The fourth level of control is achieved by phosphorylation of transcription factor components, which enhances the ability of complexes containing these factors to activate transcription. The differential composition and activities of transcription factor complexes provide one mechanism whereby differential cytokine production patterns can be achieved. Finally, transcription factors that act both positively and negatively have been demonstrated, as have both cooperative and competitive interactions. This can therefore be a point of integration of synergistic or counteractive signals in the induction of cytokine expression.

RNA processing and transport

Regulation of cytokine expression can potentially occur at the level of splicing, capping, polyadenylation and/or transport of mRNA from the nucleus to the cytoplasm. Stimulus-dependent effects on pre-mRNA splicing have been shown for IL-1 β and IL-2. Alternative splicing of some cytokines occurs and, for IL-4, can yield an inhibitor of IL-4-mediated stimuli (see below). Transport of IL-2 mRNA can be affected by CD28-mediated costimulation in T cells.

mRNA degradation

Post-transcriptional mRNA decay is a major level of regulation of expression for many inducible cytokines. Rapid mRNA deadenylation and degradation are mediated by sequence motifs in the 3' untranslated region of the transcript. The key motif has recently been redefined from AUUUA to UUAUUUA(U/A)(U/A). Multiple constitutively expressed or inducible proteins capable of binding these motifs have been partially characterized but their precise function(s) is unknown. There is some evidence that the degradation of certain cytokine mRNAs may also be achieved by endonucleolytic cleavage involving RNases with incompletely understood sequence preferences.

Translation and secretion

Translational control of cytokine expression has been less frequently described but is a major level of regulation for certain cytokines, including IL-1, TNF α and β and TGF β . Sequence elements in both the 5' and 3' untranslated regions of cytokine mRNAs can positively or negatively influence translation rates. Cytokines can also be modified post-translationally by glycosylation and/or phosphorylation and, although glycosylation does not appear to be essential for biological activity, differences in the

activities of different cytokine glycoforms have been described. Both IL-1 α and - β are synthesized as pro-hormones, which, in the case of IL-1 β , must be cleaved to be biologically active. TGF- β is similarly secreted as an inactive latent complex which requires specific extracellular activation. Secretion of a splice variant of IL-4 (see above) or a homodimer of the IL-12 p40 chain can antagonize the activity of the normal forms of these cytokines. Inducible cytokine secretion can occur in some cells, notably mast cells and platelets, through release of preformed molecules stored in granules.

Several mechanisms serve to focus or sequester cytokines at the site of production. For example, some cytokines (including IL-1 α , TNF α , lymphotoxin α/β trimers and M-CSF) can be expressed as membrane-bound forms, and many secreted cytokines are bound nonspecifically by extracellular matrix. Directional secretion of IL-4 by T cells towards the region of contact with antigen-presenting cells has also been reported and may be an important general mechanism for maximizing the effects of transiently-produced cytokines in tissue microenvironments.

CYTOKINE INHIBITORS

Carlo Chizzolini and **Jean-Michel Dayer**, Division of Immunology and Allergy, University Hospital, Geneva, Switzerland

Cytokines deliver information to target cells when the appropriate receptors are expressed at the cell surface. Upon cytokine binding and cytokine-induced receptor aggregation, the signal is transduced resulting in gene activation and/or phenotypic or functional changes of the target cell. Thus, cytokine activity ultimately depends on its concentration in the microenvironment (i.e. in the extracellular fluid or in membrane-bound form) and on the expression level of specific receptors at the surface of

responding cells. Cytokine inhibitors may act in several ways and at multiple levels, inhibiting cytokine synthesis and release, modulating the amount of biologically active cytokine in the extracellular milieu, and inhibiting the capacity of the target cell to respond to cytokines (**Figure 1**). For a better understanding of the field of cytokine inhibitors, it is important to realize that they were discovered as natural products in biological fluids, blocking interleukin-1 or tumor necrosis factor.

Levels of inhibitory mechanisms

Cytokine production (see Figure 1) can be regulated at the gene level (1a), where promoters or inhibitors of transcription act, and at the mRNA level (1b), where the stability and translation of the message can be modulated by hormones, cytokines or drugs. Members of the MAP kinase family and serine-threonine kinase are among the factors involved in the signal transduction pathway for cytokine production and are therefore the target of drug intervention. In addition, the intracellular protein level can be affected by proteases (1c) needed to process propeptides into mature, functionally active polypeptides or to release cytokines from the cytoplasmic membrane. Once released, the biologically active amounts of a cytokine can be modulated by soluble ligands (2), in the form of nonreceptor cytokine-binding proteins (2a), autoantibodies (2b), soluble specific receptors (2c), and by proteolytic enzymes (2d). Soluble receptors can be derived from proteolytic cleavage of membrane-bound receptors (i.e. tumor necrosis factor α (TNF α) and interleukin 1 (IL-1) receptors), by alternative splicing of the mRNA coding for membrane receptors (i.e. sIL-4R), and by post-translational modification (i.e. glycosyl phosphatidylinosi-

tol (GPI)-anchored receptors by removal of the signal peptide). All the soluble ligands with cytokine-binding capacity potentially participate in the regulation of cytokine delivery and homeostasis. Whether their net effect is inhibition or enhancement of the cytokine action may depend on specific characteristics of the binding protein and on the kinetics of binding. As long as the cytokine is prevented from reaching membrane receptors, inhibition is maintained. However, soluble receptors and other soluble ligands can actually increase the concentration of cytokines in body fluids by increasing their stability and decreasing their proteolytic degradation. Upon dissociation from soluble ligands, biologically active cytokines can again reach and activate specific membrane receptors. Thus, soluble ligands can function as carriers of cytokines. Binding affinity therefore plays an important role in determining the relevance of soluble ligands in cytokine homeostasis. For instance, very high concentrations of soluble receptors are needed to effectively compete with membrane receptors when these receptors are associated with transducing subunits which increase their binding affinity (i.e. sIL-2R α). In contrast, the soluble forms of single chain receptors (sIL-1R; sTNF-R) are strong competitors and lesser amounts of them are required.

Figure 1 Diagrammatic representation of the various levels at which cytokine inhibitors can act (see text for details).

An additional mechanism of inhibition is generated by molecules that specifically bind to membrane receptors (i.e. IL-1Ra) thus competing with biologically active cytokines for binding. Such receptor antagonists (3b) are unable to generate a signal upon binding resulting in the inhibition of the cytokine activity. The receptor expression level at the surface of the target cell (3a) can be affected and regulated by several stimuli, including the stage of activation of the target cell, hormones, cytokines, drugs. Furthermore, the expression of surface receptors that bind with high affinity but do not signal has been documented (3c). Lastly, the signal transduced upon receptor occupancy (3d) can be regulated by concomitant stimuli delivered by other cytokines or drugs. Finally, cytokine bioactivity can be controlled by transcription-factor inhibitors (e.g. NF- κ B). A peculiar characteristic of cytokines is that they generate and act within a network through synergistic and antagonistic interactions. The balance or homeostasis between agonists and antagonists (or inhibitors) is probably more important than their absolute amounts. All the above levels of cytokine regulation have to be considered in order to understand the cytokine network and the mechanisms of cytokine inhibition within. The following sections contain typical examples illustrating known mechanisms involved in the inhibition of cytokine activities (Table 1). However, the regulation of cytokine production by xenobiotics will not be discussed.

Inhibition of interleukin-1

IL-1 is a potent mediator of inflammation affecting the function of many different cell types. At least five different levels of regulation of IL-1 activities have been documented.

IL-1 receptor antagonist (IL-1Ra), a glycoprotein of 22 000 molecular weight, is a member of the IL-1

gene family and binds IL-1R type I, a receptor capable of transducing signals, with similar affinity to that of IL-1 α and IL-1 β . However, unique in cytokine biology, no signal is transduced upon IL-1Ra binding to IL-1R. It is speculated that no signal is transduced because IL-1Ra fails to bind the IL-1 receptor accessory protein (IL-1R-AcP), thus inhibiting the formation of the IL-1 receptor heterodimer complex required for signal transduction. IL-1Ra is produced by the same cells that secrete IL-1; however, the expression of IL-1Ra is regulated by different types of stimuli including complexed IgG and anti-inflammatory cytokines. In addition, IL-1 and IL-1Ra exist in various forms (i.e. secreted and intracellular). The actual extent of the inhibitory activity of IL-1Ra *in vivo* is unclear. Due to the fact that occupancy of only a few membrane IL-1 type I receptors is sufficient to generate a biological response, the concentration of IL-1Ra (compared to IL-1) needed to interfere with IL-1 activity has to be at least 100 times higher.

IL-1R type II binds with high affinity both IL-1 β and IL-1Ra. However, it lacks a cytoplasmic domain and does not transduce signals. Therefore, this type of receptor functions as a decoy, inhibiting IL-1 β activities.

Both type I and type II IL-1 receptors exist in soluble form after proteolytic cleavage of the full length membrane forms. The rank of binding to type II IL-1 soluble receptor is IL-1 β > IL-1 α > IL-1Ra and for type I IL-1 soluble receptor it is IL-1Ra > IL-1 α > IL-1 β . IL-1 soluble receptors with bound IL-1 species do not have signaling capacity; instead, they act by decreasing the levels of biologically active IL-1.

Naturally occurring autoantibodies that bind IL-1 α (but not IL-1 β) have been described in about 25%

Table 1 Mechanisms involved in cytokine inhibition

Level	Process	Mechanism
Cytokine synthesis and secretion	Transcriptional regulation	Transcription factors
	mRNA stability	3'-AU-rich motifs
	Transcription/translation	Hormones (e.g. corticosteroids) Cytokines
	Processing and release	Proteases (e.g. metalloproteases)
Expression of membrane cytokine R	Competition	Nonsignaling receptors (e.g. IL-1R type II)
Interaction of cytokines with membrane R	Interference	Soluble cytokine R
		Receptor antagonists (e.g. IL-1Ra)
		Nonreceptor cytokine-binding protein (e.g. uromodulin)
		Anticytokine autoantibodies

of normal individuals, and some of them have proved to neutralize IL-1 α *in vitro*. The prevalence of such autoantibodies is increased in some inflammatory autoimmune diseases (e.g. rheumatoid arthritis). Their function *in vivo* remains unclear but they could contribute to regulating the levels of bioactive IL-1 α so that disease activity may inversely correlate with the amounts of blocking autoantibodies.

The production of IL-1Ra can be enhanced by anti-inflammatory cytokines such as IL-4, IL-13, IL-10, and transforming growth factor β (TGF β). These cytokines increase IL-1Ra production while decreasing lipopolysaccharide (LPS)-induced IL-1 production *in vitro*. The levels of type II IL-1 soluble receptor are also increased in response to IL-4. Thus, the coordinate expression and upregulation of the receptor antagonist and of type II soluble receptor may regulate and decrease the responses to IL-1. *In vivo*, infusion of IL-4 results in the suppression of gene expression and synthesis of inflammatory cytokines while inducing high levels of IL-1Ra and type II soluble receptor.

Large amounts of IL-1 α may exist at the intracellular level, both in the cytoplasm and in the nucleus, in the form of pro-IL-1 α which is processed by the interleukin-1 converting enzyme (ICE), in turn controlled by inhibitors. This is well documented in keratinocytes where pro-IL-1 α is thought to drive terminal cell differentiation. An intracellular form of IL-1Ra (icIL-1Ra) has also been documented in keratinocytes and monocytes, that is supposed to regulate pro-IL-1 α -driven cell proliferation and differentiation. IL-1Ra, easily detectable in human serum, is also produced by hepatocytes, behaves as an acute-phase protein and probably is an important factor in host defense. Its monitoring could be useful in assessing inflammatory diseases.

Interestingly, several vaccinia strains of the poxviruses have encoded in their genome the capacity to secrete a soluble protein which binds to IL-1 β selectively and with high affinity. Although structurally different, this viral protein shares 33% homology with human IL-1 receptors at the amino acid level. The virus strains capable of releasing this protein are less virulent, and it is speculated that evolutionary selective pressure has favored the development of these strains because they are substantially less pathogenic, thus ensuring the survival of both host and virus. These data emphasize the importance of IL-1 in both protection and pathology. They stress the relevance of fine tuning the levels of bioactive agonistic IL-1 and explain the redundancy of the molecules implicated in its control.

Inhibition of tumor necrosis factor and lymphotoxin

At the ligand level, an important control mechanism for the production of TNF α is the release of the membrane-bound (26 kDa) precursor controlled by the metalloproteinase TNF α -converting enzyme (TACE). TNF α and lymphotoxin (LT α) (previously called TNF β) act after binding to membrane-bound p55 (or p60, or type I) and p75 (or p80 or type II) receptors expressed by numerous types of cells. Both exist in soluble forms, detected *in vitro* and *in vivo*, and are released from the cell surface after proteolytic cleavage, possibly mediated by an unidentified metalloproteinase. Of the two receptors p75 is shed more frequently. Among the stimuli that enhance TNF receptors shedding is TNF α itself. Since soluble receptors have a longer half-life than TNF α , it is easier to detect in body fluids the levels of soluble TNF receptors which reflect previous or ongoing TNF responses. The affinity of soluble receptors for TNF α and LT α nearly equals that of membrane receptors. Thus, they may act as buffers, although they may also act as carriers and prolong TNF α bioavailability. Soluble TNF receptors circulate in nanogram amounts in human blood, but are increased in various inflammatory diseases and control the bioactivity of TNF α . Chimeric protein molecules consisting of an Fc portion of the human IgG1 coupled to p55 or p75 TNF soluble receptors are at present being evaluated in clinical trials to treat chronic inflammatory autoimmune disorders such as rheumatoid arthritis and severe acute inflammatory or infectious diseases.

Inhibition of interleukin-4

IL-4 signals through an heterodimeric receptor composed of the IL-4Ra and the IL-2 R γ_c chain. IL-4Ra exists in soluble form and protects IL-4 from proteolytic degradation. Because IL-4 soluble receptor has a lower affinity for IL-4 than the cell-bound receptors it seems likely that the soluble form serves as a carrier of IL-4, facilitating its presentation to cell-bound receptors. In addition, an alternative splice variant of human IL-4, called IL-4 δ -2, inhibits *in vitro* IL-4-stimulated T cell proliferation. This splice variant seems to be preferentially expressed in the thymus and bronchoalveolar lavage cells. This finding suggests that the generation of cytokine variants by alternative RNA splicing due to exon-deletion mechanism might give rise to receptor antagonists and may be an important mechanism for the regulation of cytokine activity.

Inhibition of interleukin-12

The biologically active IL-12 is a heterodimer composed of two disulfide-linked subunits, p35 and p40. The naturally occurring p40 homodimer which retains the capacity to bind the IL-12 receptor prevents signaling, thus acting as an antagonist of the IL-12 heterodimer.

Ambivalence of the two soluble IL-6 receptors: inhibitory activity of gp130 receptor

gp130 is the common receptor β subunit shared by IL-6, ciliary neurotrophic factor (CNTF), oncostatin M, IL-11, cardiotrophin 1, and leukemia inhibitory factor (LIF). Its soluble form has been shown to inhibit the action of IL-6 *in vitro*. This is interesting because the soluble IL-6R α acts in the opposite way. Indeed, upon binding to IL-6 soluble IL-6R α allows signaling through membrane-bound gp130.

Anticytokine autoantibodies

Natural anticytokine autoantibodies occur in 10–25% of normal donors and with increased prevalence and titers in patients with autoimmune or rheumatic disorders. Antibodies specific for IL-1 α , IL-6, TNF α and type I interferon have been principally reported. However, the capacity to act as blocking antibodies is still debated for many of them.

Nonreceptor proteins

Uromodulin, an 85 kDa protein found in the urine of pregnant women binds both IL-1 and TNF α , thus acting as a nonspecific, partial inhibitor whose mechanism of action is still unknown. In contrast, serum α_2 -macroglobulin is mentioned as a transporter rather than an inhibitor. It binds several cytokines (i.e. IL-1, IL-2, IL-6, PDGF, FGF β) and inhibits proteases. The role of nonreceptor proteins *in vivo* is far from clear.

Inhibitory biological activities

As mentioned above, cytokines and their receptors are enmeshed in a network of agonistic, synergistic and antagonistic biological activities. A single cell type can be the target of multiple cytokines with similar or opposite effects. In turn, the target cell responds to received stimuli by releasing in the milieu soluble products that may affect the original producer cell. Thus, positive and negative feedback loops regulate the responses to cytokines.

Concerning the immune response, the concept of T_H1 and T_H2 cells has developed in recent years. These are T lymphocytes characterized by the polarized production of cytokines with opposite functions. Thus, T_H1 cells exclusively produce the T_H1 cytokines interferon γ (IFN γ), lymphotoxin and IL-2, whereas T_H2 cells produce the T_H2 cytokines IL-4, IL-5, IL-10 and IL-13. Broadly speaking, in terms of B cell help, of proinflammatory and anti-inflammatory activities, T_H1 and T_H2 cytokines can be considered reciprocal inhibitors. Although obviously incomplete and not restricted to the T helper lymphocyte subset, this dichotomic and simplified division provides a handle on the complexity of the regulation of the immune system. For example, both IL-4 and IL-10 inhibit the release and function of IL-1, TNF α and other proinflammatory cytokines such as IL-8 and matrix metalloproteinases (MMP). Conversely, they increase the secretion of natural cytokine inhibitors such as IL-1Ra, soluble IL-1 receptors and soluble TNF receptors. Thus IL-4 and IL-10 may serve as feedback control mechanisms of the activities of several proinflammatory cytokines. Beside releasing soluble mediators, TH1 and TH2 cells cross-regulate inflammatory responses also upon direct cell-cell contact with monocytes. TH1 enhance the production of proinflammatory cytokines while TH2 favor the production of anti-inflammatory cytokines.

Therapeutic implications

Based on the aforementioned concept, a more rational approach to interfering with acute and chronic human diseases has been developed that has led to numerous clinical trials which may culminate in clinical use. The general principle is that the absolute level of a cytokine has to be analyzed in terms of balance with regard to that of its natural inhibitor(s). Thus, IL-1Ra, sIL-1R and sTNFR may guard against the proinflammatory cytokines. IL-4 and IL-10 are at present being assessed in clinical trials. An attempt to increase local expression of cytokine inhibitors has also been made through gene therapy. At present, the overexpression of IL-1Ra is being tested in animal models of arthritis.

Recombinant forms of natural inhibitory cytokines such as recombinant IL-1Ra, recombinant soluble TNF-R p55 or recombinant soluble TNF-R p75 with human Fc constructs (rTNFR:Fc p60 or rTNFR-Fc80 fusion protein), short motifs of such peptides, or polyethyleneglycol (PEG-rsTNF-RI) or TNF-binding protein (TNF-bp-PEG) are now available in large amounts and their pharmacokinetics and safety profiles are being tested. Approaches using

gene therapy to reach the local site of the inflammatory destructive lesion are under investigation. A complete assessment of the efficacy of these new agents will comprise their evaluation for long-term treatment, not only in patients with refractory and longstanding disease, but also in those in the early stages of disease. Thus, potentially better therapies are provided along with a better understanding of the pathogenetic mechanisms of immune inflammatory diseases.

CYTOKINE RECEPTORS

Brian MJ Foxwell, James B Crawley and Theresa H Page, Kennedy Institute of Rheumatology, Sunley Division, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Cytokines exert their biological effects on responsive tissues by binding to high-affinity cell surface receptors. Prior to 1988, little was known of the cytokine receptors, as only the CSF-1 (colony-stimulating factor) receptor (R) and the low-affinity binding chain (α chain) of the interleukin (IL-) 2 R had been cloned and characterized. However, the cloning, purification and large-scale production of cytokines and the rapid development of expression cloning technologies have led to the molecular characterization of their receptors. In general, the cytokine receptors share some common characteristics, a high affinity for ligand (K_d 10^{-11} – 10^{-9} M) and normally very low levels of expression, typically a hundred to a few thousand receptors per cell. The majority of cytokine receptors are glycosylated integral type 1 (N-terminus extracellular, C-terminus cytoplasmic) membrane proteins. Functional cytokine receptors are also typically complex structures requiring the formation of homologous or heterologous associations between receptor chains. The exceptions to this are the receptors of the chemokine family, e.g. those for RANTES and IL-8. These receptors belong to the serpentine superfamily that span the membrane seven times and do not appear to form multimeric complexes.

Apart from these general features the characterization of the cytokine receptors has led to elucidation of a variety of structural features that has permitted the identification of many distinct receptor families (Table 1). In some cases these families can be further subclassified by the nature of the subunit structure used in the active receptor (see below).

Distribution of receptors

As most cytokines were originally isolated from the hematopoietic system, initial studies on receptor expression largely concentrated on this tissue. However, with time and the generation of suitable reagents, cytokine receptors have been detected in many other tissues. The expression of individual cytokine receptors on different cell types is highly variable. For instance, the receptors for IL-2, IL-3, IL-5, IL-7 and IL-9 have so far been mainly restricted to the cells of the hematopoietic system, whereas the receptors for IL-1, IL-4, and IL-6 are more widely expressed on other cells (e.g. fibroblasts), and the receptors for TNF (tumor necrosis factor) and

IFN α/β (interferon) are found on most cell types. However, it is likely that with further studies and improved quantitative technology our perception of the tissue distribution of some cytokine receptors will change considerably.

Receptor structure: five major families

Hematopoietic growth factor receptor family (cytokine receptor class I)

The hematopoietic receptor family (cytokine receptor class I) forms the largest group of cytokine receptors. This family includes the receptors for IL-2/IL-15 (β chain), IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, GM-CSF (granulocyte-macrophage colony-stimulating factor), G-CSF (granulocyte colony-stimulating factor), OSM (oncostatin M), LIF (leukemia inhibitory factor), GH (growth hormone), Epo (erythropoietin), prolactin, CNTF (ciliary neurotrophic factor), thrombopoietin (c-mpl) and CT-1 (cardiotropin 1), as well as nonligand binding accessory subunits such as the common gamma (γ c) chain, gp130 and KH97 (see below). These receptors all share a degree of structural homology in their extracellular domains, and in particular have a number of conserved cysteine residues. In addition, the extracellular domains express one or two copies of a common pentameric motif, Trp-Ser-X-Trp-Ser, contained within a fibronectin type III domain. The precise role this motif plays in receptor function is unclear. Between the cytoplasmic domains of these receptors there is generally little homology except for two short amino acid sequences, known as the box 1 and box 2 regions, which are expressed by most receptors. The box 1 region provides the site of interaction for the Janus family of tyrosine kinases. The role of the box 2 region is unclear. None of these receptors have any identifiable enzymatic activity but intracellular tyrosine kinases of both the *src* and/or the Janus family of tyrosine kinases can associate with these receptors (see below).

A general feature of these receptors is oligomerization of receptor subunits, often leading to the conversion of lower affinity binding of the ligand-specific chain to a higher affinity. Another feature of receptor assembly is the promiscuous use of common receptor subunits by various groups of functionally related cytokines. Three such families have so far been defined. The receptors for IL-2, IL-4, IL-7, IL-9 and

Table 1 Cytokine receptor families

<i>Family</i>	<i>Members</i>	<i>Comments</i>
HGFR/class I	IL-2R, IL-4R ^a , IL-7R ^b , IL-9R, IL-15R ^c IL-3R ^d , IL-5R, GM-CSFR IL-6R ^e , IL-11R, LIFR, OSMR, CNTFR, CT-1R IL-12R G-CSFR, EpoR, prolactin R, GHR Thrombopoietin-R (c-mpl) IL-13R	All associated with γ_c chain All associated with common β chain All associated with gp130 Two chains β_1 , β_2 related to gp130 Homodimer formation Association unknown Forms complex with IL-4R
IFNR/class II	IFN α / β R, IFN α R, IFN γ R, IFN γ R accessory IL-10R ^f	Forms heterodimers Forms homo- and heterodimers Homodimer
TNFR family	LT/TNF-R (p55, p75), CD27, CD30, CD40, 4-1BB, Fas, LT β R, OX40, NGFR	Forms homodimers/oligomers; ligands mainly cell surface bound
Ig superfamily (no tyrosine kinase)	p60 IL-1R, p80 IL-1R, IL-1R-associated protein, IL-6R	IL-1R and IL-1R-associated protein Forms heterodimers
Ig superfamily (tyrosine kinase)	PDGFR($\alpha\beta$), FGFR (1,2,3,4), CSF-1R (c-fms), SCFR/c-kit	Forms oligomers on ligand binding
Tyrosine kinase/non-Ig superfamily	EGFR, insulin R, insulin-like growth factor R, neurotrophin receptors (trkA, B, C)	Forms oligomers on ligand binding
Serpentine/chemokine receptor	High-affinity IL-8R, low-affinity IL-8R, Duffy antigen, MIP-1 α R (CC-CKR-5)	Seven transmembrane spanning regions
IL-17R	Unknown	
Serine/threonine kinase	TGF β RI, TGF β RII	Forms heterodimers
Proteoglycan	TGF β RIII	
IL-2R α , IL-15R α		Structurally similar to CD35 ⁺ E-selectin

^aAlso forms complex with IL-13R.

^bBinds another ligand TSLP (murine only).

^cAlso uses IL-2R β chain.

^dAssociates with two forms of β chain in mouse (AIC2A/B).

^eAlso has Ig superfamily domains.

^fAdditional chain thought to exist.

IL-15 all utilize the γ_c chain. Members of a second group, containing the IL-3, IL-5 and GM-CSF receptors, all utilize the common β chain (KH-97/AIC2A/B), and those of a subfamily that contains the receptors for IL-6, IL-11, LIF, OSM, CNTF and CT-1 all share gp130. It is likely that the complexity of these receptor subfamilies may grow, as the IL-4R can associate with the IL-13R instead of the γ_c to form an alternative IL-4/IL-13 receptor.

Interferon receptor family (cytokine receptor class II)

A smaller family of receptors has been termed the interferon or cytokine receptor type II family, and includes the IFN α / β R, the IFN α R, the IFN γ R, the IFN γ R accessory protein and the IL-10R. This family is characterized by the presence of either one (IFN α / β R, IFN γ R, IFN γ R accessory protein, IL-10R) or two (IFN α R) homologous regions of 200 amino acids in the extracellular domain, each of

which contains two fibronectin type III domains. As with the class I family, these receptors have no integral enzymatic activity but can associate with the Janus family of tyrosine kinases. The IFN α / β R and the IFN α R form heterodimers, whereas the IFN γ R and the IL-10R homodimerize. In addition, the IFN γ R requires the IFN γ R accessory protein to form a functional receptor.

TNF receptor family

A third group is represented by the type I (p60/p55) and the type II (p75/p80) TNF/LT (lymphotoxin) receptors. This family also includes the NGFR (nerve growth factor receptor), CD27, CD30, CD40, the LT β receptor, OX40, 4-1BB and the Fas antigen. These proteins are characterized by the presence of three or four cysteine rich repeats of about 40 amino acids in their extracellular domains. With the exception of the two TNFRs and the NGFR, the other members of this family have not previously been

considered to be cytokine receptors, having ligands that themselves are expressed on the cell surface rather than being soluble proteins. In addition, the TNFRs, in particular the type II receptor, can also bind surface-bound TNF. A common feature of this family is that activation involves oligomerization. In the case of the TNFR this involves the homotrimerization of the receptor on binding of the trimeric ligand(s). Another feature of the TNFR is the presence of two distinct receptor forms that are degenerate for the binding of TNF and LT. As with the type I and type II cytokine receptor families, the TNF family has no intrinsic enzymatic activity and does not appear to associate with any of the known families of tyrosine kinases.

Immunoglobulin and receptor tyrosine kinase superfamily

The fourth group of receptors belong to the immunoglobulin (Ig) superfamily of proteins. These receptors have multiple Ig-like disulfide bridge-stabilized subdomains in their extracellular portion and include the p80 IL-1R (type I), the IL-1R-associated protein and the p60 IL-1R (type II), as well as the IL-6R (which also has features of the cytokine receptor class I family). The p80 IL-1R and the IL-1R-associated protein form active heterodimers. These receptors have no integral enzymatic activity.

Another group of receptors that also contain Ig-like structural domains in their extracellular region are a number of growth factor receptors that possess a tyrosine kinase domain in their cytoplasmic region. These include the PDGF (platelet-derived growth factor) receptor (two receptor forms α and β), FGFR-1, -2, -3, -4 (fibroblast growth factor receptor), CSF-1R (colony stimulating factor 1 receptor) and SCFR/c-kit (stem cell factor receptor). On ligand binding, receptor homodimer and heterodimer formation results in the activation of the tyrosine kinase.

Another group of receptors which contain tyrosine kinases includes the EGFR (epidermal growth factor receptor), which also binds TGF α , the insulin R, the insulin-like growth factor R and the neurotrophin R (three forms; trkA, trkB and trkC). These receptors do not have Ig-like domains in their extracellular region. Ligand binding induces receptor oligomerization and activation of the tyrosine kinase.

The chemokine receptors

The last major receptor family are the serpentine receptors. These molecules have seven transmembrane spanning regions and are the receptors for the chemotactic cytokines. Several receptors have been identified, including a high-affinity IL-8R, a low-

affinity IL-8R and a MIP-1 α receptor. There appears to be some degree of degeneracy in ligand binding by these receptors. For example, the low affinity IL-8R also binds the related GRO and NAP-2 chemokines, and the MIP-1 α receptor also binds RANTES. The erythrocyte Duffy antigen also has a serpentine structure and binds IL-8 and related chemokines. The cytoplasmic regions of this receptor family associates with heterotrimeric G proteins which are activated on ligand binding.

Other cytokine receptors

In addition to the cytokine receptor families featured above, there are a few cytokine receptors that fall outside of these categories. These include the α chains of the IL-2 and IL-15 receptors, which share certain structural features with each other and with CD35 and L-selectin. The TGF β (transforming growth factor) receptors I and II are similar to each other in that they have a serine/threonine kinase in their cytoplasmic domains. They are also related to the activin receptors. Lastly, the TGF β R type III has a proteoglycan-like structure. This receptor does not appear to be involved directly in signal transduction. The structural variety of the cytokine receptors is likely to increase further as the latest addition to the cytokine family, IL-17, also has a receptor unrelated to any detailed above.

Cytokine receptor signaling

For many classes of cytokine receptors the first detectable intracellular signaling events are the tyrosine phosphorylation of proteins (Figure 1). This tyrosine kinase activity is either provided by the integral tyrosine kinase domains of the receptors, as for the PDGFR and EGFRs, or by the recruitment to the receptor of intracellular kinases. For example, the src family of tyrosine kinases (lck, fyn, lyn, hck) are recruited by many members of the class I family, while the Janus tyrosine kinase family (Jak1, Jak2, Jak3, Tyk2) are recruited by receptors of both the class I and the class II families. Tyrosine kinase activation appears to occur as a consequence of receptor homo- or hetero-oligomerization and is often accompanied by the phosphorylation of tyrosine residues in the intracellular domain of both the receptors and kinases themselves. The kinases in turn phosphorylate and activate other intracellular enzymes, such as phosphatidylinositol-3' kinase or PLC γ . These enzymes are brought into the proximity of the tyrosine kinases by binding via their SH2 domains to the tyrosine phosphorylated receptors. Another class of proteins that binds to the phosphorylated receptors are the SH2 and PTB

Figure 1 Signaling mechanisms induced by tyrosine kinase, class I and class II cytokine receptors. P, Tyrosine phosphorylation; PTK, protein tyrosine kinase.

containing 'adapter' proteins such as Shc and Grb2, which in turn bind other cellular proteins (which may become kinase substrates) either by SH2 or SH3 interactions (SH3 domains bind proteins with proline-rich sequences). A third class of proteins that can interact with tyrosine phosphorylated receptors are the STAT (1–6) (signal transduction and activation of transcription) proteins. The STATs are substrates for the Janus kinases and homodimerize or heterodimerize on phosphorylation, after which they migrate to the nucleus and bind DNA. The STATs also require serine/threonine phosphorylation for transactivational activity.

The activation mechanism of the TNF receptor family and the IL-1R is less clear: as yet, no tyrosine kinases have been shown to associate with these receptors. The cytoplasmic domain of the TNF receptor has been shown to associate with several proteins termed TRAP (TNF receptor-associated protein), TRAF 1, 2 and 3 (TNF receptor-associated factor), TRADD (TNF receptor-associated death domain) and FAD (Fas-associated death domain). The functions of these proteins is still under investigation, although the TRAFs and TRADD and FAD are involved in NF κ B activation and TNF-induced apoptosis. The chemokine receptors signal via the activation of receptor-associated trimeric G proteins where both the α subunit and the $\beta\gamma$ complex can have functional activity. Distal targets include PLC β and adenylate cyclase, the activation of which leads to increases in intracellular calcium and cAMP.

Distal events in cytokine signaling generally involve the activation of small monomeric G proteins

(e.g. p21 ras), the production of signaling lipids such as diacylglycerol (DAG), phosphatidylinositol-3' phosphates and ceramide (by the action of sphingomyelinase). The effectors of the monomeric G proteins and the various lipids are a number of serine/threonine kinases such as those within the PKC family, c-raf and others. Many of these kinases are organized into cascades, leading to the activation of p42/44, p38 and p54 mitogen-activated protein kinases (MAPKs). The substrates for many of these kinases are transcription factors such as ATF-2, c-Fos, c-Jun and Elk-2 which are activated as a result of phosphorylation. Other key kinases involved in cytokine signaling are the p70S6K and I κ B kinases (essential for the activation of NF κ B). However, the mechanism leading to the activation of these kinases remains largely obscure. It is clear that cytokine receptors are involved in the parallel activation of multiple signaling pathways with different functional end-points. The full elucidation of the relationship between the activation of the various pathways to the different functions of a given cytokine is a future challenge.

Cytokine receptors and disease

High levels of cytokine receptors have been observed on tumor cells. For example, human T cell lymphoma virus 1 (HTLV-1)-infected cells (acute cutaneous lymphoma) express high levels of the IL-2R α chain, whereas plasmacytomas have been found to express high levels of the IL-6R. Another intriguing area where cytokine receptors may play a role is in

viral pathogenicity. A number of homologs of cytokine receptors have been identified encoded in viral genomes, either as membrane-associated or as soluble-receptor forms. It is anticipated that by the inappropriate expression of virally encoded receptors, or the secretion of soluble receptors as potential inhibitors, the cytokine network can be manipulated to the advantage of the virus. A third area in which cytokine receptors are implicated is that of congenital hematopoietic disease. X-linked severe combined immunodeficiency disorder (X-SCID), for example, is the result of genetic defects in the expression and function of the γ c chain which results in a failure of B lymphocyte development. Furthermore, congenital defects in the expression of gp39/CD40 ligand are associated with X-linked hyper-IgM syndrome. Cytokine receptors have also been shown to have a key role in the pathophysiology of human immunodeficiency virus (HIV) infection. It has been shown that the chemokine receptors, CCR-5 and CCR-3, act as cofactors for virus entry into macrophages, whereas the LESTR/SDF-1 receptor is required for the infection of T cells. Moreover a naturally occurring mutation of CCR-5 appears to confer resistance to acquired immune deficiency syndrome (AIDS).

CYTOKINE RECEPTORS, SOLUBLE

David Wallach, Department of Membrane Research and Biophysics, Weizmann Institute of Science, Rehovot, Israel

Cell-bound and soluble forms of ligands and receptors

The term 'soluble receptors' (SRs) is an apparent paradox. Originating from the field of hormone research, the terms 'receptors' and 'ligands' initially stood for features that are peculiar to the endocrine mode of intercellular communication. In this mode, the communicating cells play different roles; cells of

the endocrine gland serve as the source of the message and the cells of the target tissue respond to it. Accordingly, the ligands and the receptors that participate in this communication also have distinct features, the ligand molecules serving solely to transfer the information and thus occurring only in a soluble, secreted form, and the receptors acting solely for receiving this information and thus, by definition, occurring solely in association with the target cell.

With the increasing knowledge of the cytokines and the ways in which they act, it became clear that in most cases transfer of molecular information does not occur, as in endocrine regulation, between cells that serve solely an effector or a target role. In fact, all nucleated cells serve both as producers of cytokines and as targets for their action. Nor is the transfer of molecular information restricted only to interaction between remote cells. Much of the action of cytokines occurs in close proximity to their site of formation, namely, in autocrine, juxtacrine and paracrine ways. The physical states and functional roles of receptor and ligand molecules may therefore be quite different from those that, prior to the era of cytokine research, were considered as definitive. Both receptors and ligands can occur in cell-bound as well as in soluble forms. Moreover, some cell-bound molecules have the ability to function at the same time both as receptors and as ligands. Their binding to receptors expressed on other cells results both in triggering of signaling by the latter receptors and in triggering of signals that they themselves produce (reversed signaling; illustrated in Figure 1(2)).

Another former distinction which we now view

differently concerns the functional significance of the various regions in the receptor molecule. According to the initial concepts of the way in which receptors act, their extracellular domains appeared to serve merely a subsidiary role to that of the signaling intracellular domains. The discovery of the SRs highlighted the fact that recognition of the ligand by the extracellular domain can have some functional consequences that are independent of the function of other regions in the receptor. In a few cases, this independent role of the extracellular domain can be observed even when it is still cell bound. The extracellular domain of the type II interleukin 1 (IL-1) receptor, for example, has been shown to act as a 'decoy receptor'; that is to say, it serves solely as a means of restricting the availability of IL-1 to the other (type I) IL-1 receptor, thereby decreasing signaling by it. Another example, opposite in nature, is an apparent ability of the extracellular domain of CD120b (the p75 tumor necrosis factor receptor, TNF-R) to assist binding of TNF to coexpressed CD120a molecules ('ligand passing'). However, most of our knowledge of such 'extracellular domain-specific' functions concerns SRs.

Figure 1 Structural forms and modes of action that can be attained by cell-bound and soluble forms of receptors and ligands.

In a wide sense, the term 'soluble receptors' also relates to the antibodies, whose ligand-binding portion can occur both in a soluble form (immunoglobulin, Ig) and in association with cells (the cell-surface immunoglobulins in B cells). Indeed, it was while attempting to describe the mechanisms by which antibodies are formed that Paul Erlich first suggested, about a hundred years ago, that cells are able to produce ligand-binding molecules both in soluble and in cell-associated forms (Figure 2).

Receptors known to occur in soluble form

A partial list of the receptors that are known to exist in soluble form is presented in Table 1. Some of these receptors were identified in body fluids or in the growth media of cultured cells. Others, for which specific messages exist (see below), were identified by cloning of their cDNAs. A unique example of receptors that exist only in soluble form are the 'viroceptors' – coding regions for soluble forms of cytokine receptors – found in certain pox viruses that have apparently usurped these sequences from host cells. All known SRs are derived either from single-transmembrane domain proteins or from glycosylphosphatidylinositol (GPI)-anchored cell surface proteins. Other than that, there are no evident structural or functional features common to these receptors.

Structure and mechanisms of formation of soluble receptors

The SRs whose cell-bound forms are transmembrane proteins can be formed in one of the following two ways: 1) proteolytic cleavage of the cell surface form; 2) transcription of a distinct mRNA derived by alternative splicing from the gene that encodes the cell surface receptor. Some of these receptors are formed in both ways, while the *c-kit* receptor (as well

as its ligand, the stem cell factor, which also occurs in both cell-bound and soluble forms) provides an example of a composite mechanism. It is derived proteolytically from a particular splice variant of the cell surface form in which one of the exons, which is lacking in the other splice variants, codes for the proteolytic cleavage site. Soluble forms of GPI-anchored receptors are produced by escaping the post-translational modification (removal of the signal peptide) required for anchorage, and perhaps also by phospholipase C-mediated cleavage of the anchor. They can also be formed by proteolytic cleavage of their polypeptide chain.

Traces of the mechanism by which the SRs are formed can sometimes be discerned in their amino acid sequences. Those SRs derived proteolytically from the cell surface receptors have exactly the same amino acid sequences as those found in the extracellular domains of the cell surface receptors (upstream of the site of proteolytic cleavage). On the other hand, SRs encoded by distinct messages can have additional, unique sequences, downstream of the site of alternative splicing, resulting from alteration of the reading frame. This unique sequence is usually short and nonfunctional. The only known exceptions are the antibodies, whose unique C-terminal parts (The Fc regions) are encoded by exons that are different from those found in the message for the cell surface immunoglobulins and serve unique and important functions. The viroceptors also contain regions of unique sequence downstream of the region homologous to that of the cell-bound receptors. In some cases self association of these regions results in formation of dimers of the viroceptors. Such dimers have the ability to bind to the ligand more effectively than the monomeric molecules.

The cleavage process by which SRs are formed was shown to occur following transport of the cell-bound receptor to the cell surface. In some of these cases

Figure 2 Free side-chains (circulating antitoxins) unite with the toxins and thus protect the cell. (Reproduced from Ehrlich P (1900) On immunity with special reference to cell life. *Proceedings of the Royal Society*.)

the proteases involved are soluble and are found in the extracellular milieu (e.g. elastase, released by activated granulocytes). In others, however, they are cell associated. Inhibitory effects of hydroxamic acid inhibitors on the shedding of several receptors pointed to the involvement of metalloproteases. The enzyme responsible for the shedding of TNF α (TACE) was recently cloned, and indeed found to be a metalloproteinase-disintegrin of the adamalysin family. To date, however, no other 'sheddase' has been identified, nor is there any knowledge of the specificity of action of these enzymes, except that their function seems to be restricted by some conformational features of the membrane-proximal region of the extracellular domain at which the cleavage occurs.

Both the proteolytic production of SRs and their formation as distinct splice variants can occur in an inducible manner. Often the ligand to which the soluble receptors bind serves to induce their formation, allowing the SRs to act as a feedback control mechanism.

Functions of soluble receptors

Current ideas of the function of SRs are largely speculative, being based primarily on *in vitro* effects of these molecules and only to a small extent on direct information about their *in vivo* effects.

In vitro effects

In vitro studies of SRs have revealed several different potential roles of these molecules.

1. SRs that may act as inhibitors of signaling (Figure 1(1)) All SRs bind their ligands with lower affinity than that of their cell surface forms. The binding affinity of some, for example the soluble IL-2R α , is rather low, raising doubts as to their ability to affect significantly the function of the cell surface receptors. Other SRs, however (e.g. the receptors for IL-1, IL-4 or TNF), have binding affinities high enough to allow them to compete effectively with the cell surface receptors for the ligands. Except in cases where the SRs themselves have the ability to act as initiators of signaling (see below), binding of the ligand to such SRs is expected to result in blockage of signaling.

2. SRs that may act as inhibitors of reversed signaling (Figure 1(2)) Although not documented so far, it is possible in theory that the SRs may also act as inhibitors of 'reversed signaling'. As illustrated in Figure 1(2), in the case of cell surface ligand molecules that exhibit reversed signaling (when aggre-

gated as a consequence of their binding to the cell surface receptors), binding of the monomeric SR molecules to the ligand may impede the ligand's interaction with the cell surface receptors and thus block signaling.

3. SRs that may assist the function of their ligands (Figure 1(3)) IL-4 dissociates from its SR much more rapidly than from its cell surface receptors. The soluble IL-4 receptors also provide IL-4 with protection against proteolytic degradation. Therefore, although at high concentrations these receptors can interfere with IL-4 function, it seems likely that at their physiological levels the soluble IL-4 receptors actually serve as carriers of IL-4 in the circulation and facilitate its presentation to the cell-bound receptors. A similar role was ascribed to the soluble form of the growth hormone receptor (the growth hormone-binding protein). This SR is believed to increase the functional duration of its ligand by withholding its clearance from the circulation. The soluble TNF receptors are also found to increase the functional duration of their ligands, though by a different mechanism: they prevent dissociation of the trimeric TNF molecules into inactive monomers and thus, despite their ability to compete with the cell surface TNF receptors for TNF binding, they augment those TNF effects that are slowly induced. The fact that SRs can have such positive effects on ligand function, as well as the consistent occurrence of some SRs in body fluids and the existence of mechanisms that coordinate the extent of SR formation with that of their ligands, suggests that some SRs may play an integral role (as 'buffers' or carriers) in the normal functioning of their ligands.

4. SRs that can substitute for the cell-surface receptors (Figure 1(4)) The α chain of the IL-6 receptor is devoid of signaling activity. After ligand binding, however, it associates with another transmembrane protein, gp130 (which constitutes the β chain of the IL-6 receptor as well as of other receptors of the IL-6 family); and the latter initiates signaling within the cell. In this case, the soluble forms of the two components of the receptors affect ligand function in opposite ways. The soluble form of gp130 blocks the function of IL-6 (as well as of the other cytokines that employ gp130 as part of their receptors). The soluble form of the α chain of the IL-6 receptor, however, can substitute for the cell surface receptor. The situation is similar in the case of the CNTF-R and CD14, a cell-surface lipopolysaccharide (LPS)-binding protein. Application of the soluble forms of the IL-6 receptor α chain, CNTF-R or CD14 to cells that do not express the cell surface forms of the

Table 1 Examples of known soluble forms of receptors, their presumed functions and mechanisms of formation

Receptor	Structural motifs in extracellular domain (receptor family)	Function of cell surface form	Presumed function	Soluble form		
				Proteolytic cleavage	Lack of GPI anchorage/PLC cleavage of GPI	Specific transcripts allowing cleavage
IL-1, type 1-R	Immunoglobulin-like domain	Inflammatory and acute phase reactions. Thymocyte and T cell activation	Blocks ligand binding	+		
IL-1, type II-R	Immunoglobulin-like domain	'Decoy' receptor (blocks ligand binding to coexpressed type I receptor)	Blocks ligand binding	+		
IL-2R α	Two CCP domains	T and B cell growth, macrophage activation	Blocks ligand binding	+		
IL-2R β	Cytokine receptor and fibronectin type II domains	T and B cell growth, macrophage and natural killer activation	Blocks ligand binding	+		
IL-4R	Cytokine receptor and fibronectin type II domains	Regulation of allergic reactions, IgG1 and IgE responses, growth and differentiation of hematopoietic cells, suppression of macrophage-mediated immune functions	Blocks ligand binding? 'Transport' molecule?		+	
IL-5R α	Cytokine receptor and fibronectin type II domains	Growth and differentiation of eosinophils and B and T lymphocytes	Blocks ligand binding		+	
IL-6R α	Immunoglobulin-like, cytokine receptor, and fibronectin type II domains	Acute phase protein induction, stimulation of growth of activated mature B lymphocytes, regulation of inflammation	Signals (substitutes for the cell surface receptor)	+		
gp130 (IL-6R β)	Immunoglobulin-like, cytokine receptor domain, cytokine receptor motif and four fibronectin type III domains	Acute phase protein induction, regulation of growth and differentiation of cells through effects of the various IL-6 subfamily receptors	Blocks ligand binding to the various IL-6 subfamily receptors	+		
Ciliary neurotrophic factor (CNTF)-R α	Class I cytokine receptor, GPI anchored	Growth and differentiation of cells of the neuronal system	Blocks ligand binding (substitution for the cell surface receptor)		+	
Growth hormone-R	Class I cytokine receptor	Bone growth, lactogenic, insulin-like, diabetogenic, lipolytic, protein-anabolic and sodium/water-retaining effects	Decreases rate of clearance of the ligand from the circulation	+		+

TNF, p55R (CD120a)	TNF/NGF receptor family	Signaling for cell death, growth, various inflammatory and immune functions	Blocks ligand binding; stabilizes ligand	+	
TNF, p75R (CD120b)	TNF/NGF receptor family	'Ligand passing'? (assists ligand binding to CD120a?) Cell death, growth, various inflammatory and immune functions	Blocks ligand binding (less effectively than the soluble p55-R); stabilizes ligand	+	
Fas/Apo-1 (CD95)	TNF/NGF receptor family	Cell death, growth, various inflammatory and immune functions	Blocks ligand binding	+	
NGF, p75R	TNF/NGF receptor family	Growth, differentiation and death, particularly in cells of the neuronal system	?	+	
IFN α -R (IFNAR-2)	Class II cytokine receptor	Antiviral and other defense mechanisms	Blocks ligand binding	+	
IFN γ -R	Class II cytokine receptor	Antiviral and other defense mechanisms, mainly related to interactions with cells of the immune system and among them	Blocks ligand binding	?	
CD14	Leucine-rich repeats, GPI anchored	Receptor for the complex LPS-LPS binding protein	Signals (substitutes for the cell surface receptor)	+	
CD23	Type II transmembrane, homologous to C-type animal lectins	Low-affinity IgE receptor, mediates IgE-dependent cytotoxicity and phagocytosis by macrophages and eosinophils	Acts like a cytokine with pleiotropic effects: regulates IgE production, affects macrophage activation through cytokine formation and various aspects of hematopoiesis	+	+
c-Kit	Immunoglobulin gene family	Proliferation, differentiation and survival of several hematopoietic lineages, mast cell activation	Blocks ligand binding		
T2	Viroceptor, homologous to CD120b, C-terminal dimerization region		Blocks binding of TNF α and LT α	+	
CrmC	Viroceptor, homologous to CD120b, without C-terminal dimerization region		Blocks binding of TNF α but not of LT α	+	
v-CD30	Viroceptor, homologous to CD30		Blocks binding of the CD30 ligand	+	

receptors can endow them with responsiveness to IL-6, CNTF or LPS.

5. Receptors that gain novel ligand activity upon their shedding (Figure 1(5)) Such a situation seems to exist in the case of the soluble form of CD23. In its cell-bound form, this type II transmembrane protein acts as a low-affinity receptor for IgE and also binds a cell surface protein, CD21. In its soluble form, CD23 was reported to have a variety of cytokine effects on cells. Some seem to be due to triggering of 'reversed signaling' by CD21. Others, however, seem to be mediated by another, as yet undefined, receptor. The cytokine effects of the soluble CD23 molecules are mediated by an epitope distinct from the IgE-binding site.

6. Receptors which, when in soluble form, can serve functions unrelated to signaling (Figure 1(6)) The only known example of SRs that act in this way is provided by the immunoglobulins. In their cell surface form, these molecules initiate signaling activities within the cells that express the receptors (B lymphocytes). In their soluble form, on the other hand, the immunoglobulins modulate the function of the antigens to which they bind by neutralizing or opsonizing them, by facilitating their transport, or – in the case of antigens that are expressed on the surface of cells – by causing their destruction (through effects of complement or of antibody-dependent cellular cytotoxicity). These modulatory functions are exerted through binding activities of C-terminal regions unique to the soluble immunoglobulins (the Fc region). An example of the unique binding ability of the Fc region is seen in its ability to bind to specific Fc receptors.

***In vivo* function**

As mentioned above, there is still hardly any direct information on the *in vivo* significance of the SRs. In the absence of such information, one cannot exclude the possibilities that at least some of the SRs have no functional significance at all, or (in the case of SRs that are derived proteolytically from the cell-bound forms) are merely side-products of the down-regulation of cell surface receptors upon their cleavage. A major obstacle to objective evaluation of the functional significance of SRs is the lack of technical tools for evaluating the impact of specific elimination of these molecules. Use of knockout mice or neutralizing antibodies, which have proved very useful in evaluating the *in vivo* relevance of the cytokines, cannot be applied in studies of the function of their SRs unless a way is found to maintain the function of the cell surface receptors while eliminating or

blocking the soluble forms. There are, however, a few noteworthy items of indirect evidence which suggest that SRs have important functions *in vivo*:

1. Assessment of the effect of human sera on the *in vitro* function of TNF confirmed that the soluble TNF receptors reach serum levels that are high enough to effectively suppress TNF effects (at the TNF concentrations attained in the serum).
2. Deletion of the genes that encode viroreceptors resulted in significant reduction of the pathogenesis of the viruses that harbor these genes, confirming that the viroreceptors act to suppress immunoprotective effects of cytokines.
3. As mentioned above, the soluble IL-6 receptor can substitute for the cell surface IL-6 receptor. The physiological significance of this mode of action of SRs is supported by findings about the structure of IL-12. This cytokine is composed of two subunits that show considerable sequence similarity to IL-6 and its soluble receptor, and probably act together in a way analogous to that of the IL-6–IL-6 SR complex.

Therapeutic implications

While there is only limited evidence for the physiological significance of effects of SRs observed *in vitro*, there is extensive documentation that, by injecting sufficient amounts of SRs, it is possible to reproduce artificially *in vivo* at least one of the effects that SRs can mediate *in vitro*, namely, blocking of signaling. Use of chimeric soluble receptor-Fc regions ('immunoadhesins'), or of SRs coupled to polyethylene glycol, whose clearance rate is lower than that of the natural SRs, allows prolonged maintenance of these molecules in the body and, in the case of the soluble receptors for TNF, more effective binding to the ligand (by virtue of the ability of the dimeric SRs to bind simultaneously to two protomers of the trimeric TNF molecules). Ongoing clinical trials demonstrate effective therapeutic effects of SRs in humans. Blocking of TNF function by its SRs, for example, has been found to be highly beneficial in rheumatoid arthritis and in chronic inflammatory bowel diseases.

Diagnostic implications

Data acquired in multiple studies of the *in vivo* levels of various SRs in health and disease, as well as following injection of cytokines, indicate that, as in cultured cells, formation of the SRs in the body is inducible by various stimulating agents. These data, particularly the evidence indicating that formation of several SRs is most strongly induced by the ligands

to which they bind, are consistent with the notion that formation of the SRs constitutes a physiological mode of regulation of response. This evidence prompted investigators to employ the determination of the levels of various SRs in body fluids as a diagnostic tool for assessing disease activity and for examining the involvement of the ligand of the SR in the particular pathological situation. Information gained in this way can be particularly useful in the case of SRs that have pronounced effects on the function of their ligands. Probably the most informative diagnostic parameter in such cases is the quantitative ratio of the SRs and their ligands. Indeed, there are a few reports demonstrating correlation between the severity of a particular pathological situation to which a given cytokine contributes and the occurrence of an abnormally low quantitative ratio of SR and ligand levels in the serum.

Various cancer cells are known to shed some of their cell surface proteins far more rapidly than do their normal counterparts. This may be due to an increased expression by tumor cells of some proteases capable of cleaving these cell surface receptors. Because of this particular feature of tumor cells, and perhaps also because of the activation of certain immune cells in cancer patients, their sera exhibit increased levels of certain SRs (e.g. the soluble TNF receptors, or the carcinoembryonic antigen, which is a shed form of a GPI-anchored cell surface protein). Determination of the levels of these receptors can thus be of diagnostic value not only in inflammatory and infectious diseases but also in cancer.

CYTOKINES

Marc Feldmann, Kennedy Institute of Rheumatology, Sunley Division, London, UK

Nomenclature

Low molecular weight protein mediators involved in cell growth, inflammation, immunity, differentiation and repair are now generically termed 'cytokines'. There have been many previous attempts at a suitable nomenclature, but 'cytokines' is the current most widely used compromise. Previous attempts include 'lymphokines', 'monokines' and 'interleukins'. 'Lymphokines' dates from the 1970s, for products of lymphocytes, designed to contrast with 'monokines' for products of monocytes. However, it is now known that there is considerable overlap – for example, tumor necrosis factor α (TNF α), interleukin 6 (IL-6) are made by both cell types – so this nomenclature is no longer in wide use.

'Interleukins' describes molecular messengers acting between leukocytes. The term dates from 1979, at a conference in Switzerland where it became apparent that a variety of biological activities termed 'lymphocyte-activating factor', 'endogenous pyrogen', 'catabolin' and so on, were due to molecules with similar biochemical characteristics, and the term 'interleukin 1' was adopted. Currently there are 17 molecules with a wide spectrum of activities, designated interleukins 1–17. However, there are deficiencies in this nomenclature; it is becoming abundantly clear that these molecules are often made by nonblood cells, and act on cells apart from blood cells, e.g. IL-6, IL-1.

Two other related groups of molecules have been

described: 'interferons' and 'growth factors'. 'Interferons' are molecules first described in the 1960s as protein, with nonspecific anti-viral effects. These are now known to have many other effects; thus interferon γ (IFN γ) is one of the most potent immunoregulatory mediators known; all interferons have immunoregulatory and cytostatic as well as antiviral actions. 'Growth factors' are molecules which stimulate the growth of a variety of cells. Some are more specific than others, for example granulocyte-macrophage colony-stimulating factor (GM-CSF) acts on monocytes/macrophages and granulocyte cells to promote their growth, while platelet-derived growth factor (PDGF), which is three related molecules, acts on most connective tissue cells. Hematopoietic growth factors, also termed 'colony-stimulating factors' from their initial bioassays, are, in common with the other molecules in this category, not restricted to mediating growth. They are all also involved in regulating cellular activation. Thus 'growth factors' is not an accurate terminology either.

There is a large family of chemotactic cytokines of low molecular weight (8–10 kDa) which are now termed 'chemokines'. These include IL-8, MCP-1, etc, and are grouped into two major families, depending on the position of cysteine, as C-C or C-X-C chemokines. The latter act chiefly on granulocytes, the former on monocytes and lymphocytes.

Overview of cytokine action

Unlike hormones, which are carried by the bloodstream over the whole body, cytokines are chiefly involved in local effects. Some do have systemic effects, IL-6 being the most notable, but the major physiological role of cytokines is short range, within a few cell diameters. Most cytokines are not constitutively produced, but are produced after activation of the cells. Production after activation is short lived, usually for only a few days. Typically, cytokines are effective in the picogram (pg) to nanogram (ng) per milliliter range. Studies with cytokines produced by recombinant DNA technology have shown that their half-life in the circulation is brief, reinforcing the belief that systemic distribution is not part of their normal physiology. Unlike hormones, most cytokines are not produced by specialized cells, and probably all cells produce some cytokines. T cells and macrophages are particularly rich sources of cytokines.

There is no consensus structure for cytokines. Most are glycosylated, but not all (e.g. IFN α/β , TNF α); many are in the 10–25 kDa mass range. Some cytokines are members of a family, e.g. IL-1 α

and β and the IL-1 receptor antagonist, IFN α (~15 molecules), TNF α and TNF β (also known as lymphotoxin). The family relationship is usually clear-cut if the members of the family bind to the same receptor, e.g. IL-1 α and β . Amino acid sequence homology sufficient to permit binding to a common receptor need not be very high: of the order of 30% suffices for IL-1 α and β . Recently a third member of this family, the IL-1 receptor antagonist protein (IL-1ra), has been described, which binds to the same receptor but has antagonistic effects. Should IL-1ra be considered a cytokine? If it does not activate the IL-1 receptor, most would consider it is not a cytokine but the first member of the cytokine antagonist family.

Cytokines typically induce multiple actions, on different cells. This property is often termed 'pleiotropy'. Different cytokines, e.g. IL-1 and TNF α , have closely related and overlapping actions; this is sometimes termed 'redundancy'. This is an inappropriate term, as gene knockout and antibody neutralization studies have shown that cytokines have distinct roles.

Cytokines mediate their effects after binding to high-affinity receptors on the surface of the target cell. The affinity of these receptors is generally very high, in the 10^{-9} – 10^{-11} molar range, which accounts for their potency. Receptors are usually present in low numbers (100–1000 cell $^{-1}$), but with their high affinity this clearly suffices. Increased knowledge of cytokine receptors has recently emerged from biochemical and molecular cloning studies. The cytokine-binding molecules have been described for most cytokines, nevertheless for the majority of cytokines it is not clear how signal transduction is mediated. Exceptions include the receptor for CSF-1 (M-CSF) and the PDGF receptor, which are tyrosine kinases. For the other receptors, it is becoming evident that they are multichain complexes, which assemble cytoplasmic signaling molecules upon ligand binding.

Cytokine receptors are subject to a variable degree of upregulation upon cell activation. For the IL-2 receptor α chain (p55 or Tac antigen) this is considerable, from ~0 to 10–50 000 per activated T cell in 3 days. This upregulation is usually transient, lasting only a few days in the absence of further stimulation. Upon interaction with their ligand, cytokine receptors are typically internalized, taking the ligand with them. Receptors become re-expressed after a few hours delay. Thus, after cytokine exposure, cytokine receptor expression varies considerably, initially diminishing due to internalization and then increasing due to cytokine-induced receptor upregulation.

For some cytokines, e.g. IL-1 and TNF, there are two distinct binding chains, expressed differentially on different cell types. The two TNF receptors have

Table 1 Properties of cytokines

<i>Cytokine</i>	<i>Biochemistry (kDa)</i>	<i>Properties</i>
IL-1 α	17, nonglycosylated	Activates lymphocytes, acute phase response, strongly proinflammatory, radioprotective
IL-1 β	17, nonglycosylated	
IL-2	15, glycosylated	Activator of T, natural killer (NK), B, macrophages: 'T cell growth factor'
IL-3	15, glycosylated	Multiple actions, hematopoietic cell growth – precursors of mast cells
IL-4	20, glycosylated	B cell activating factor, T cell activator, growth and stimulating factor
IL-5	45, glycosylated	B cell growth and differentiation factor, regulates production of granulocytes and macrophages
IL-6	26, glycosylated	B cell differentiating factor, activation of T and B cells, induces acute phase response
IL-7	25, glycosylated	Pre-B and pre-T cell growth factor, T cell growth factor
IL-8	8–10, family of related proteins	Involved in migration of neutrophils and T cells
IL-9	35, glycosylated	Supports growth of mast cell progenitors
TNF α	17, nonglycosylated, functions as a trimer	Proinflammatory cytokine, induces acute phase response, thrombosis, cachexia
Lymphotoxin (TNF β)	25, glycosylated, functions as a trimer	Proinflammatory cytokine, induces acute phase response, thrombosis, cachexia
IL-10	17, nonglycosylated (in humans), functions as a dimer	Inhibitor of monocyte and T cell function, activator of B cells
IL-11	23, nonglycosylated	Growth factor for plasmacytomas, hematopoietic multipotential and committed megakaryocytic and macrophage progenitor cells
IL-12	75 (heterodimer of 35 and 40 subunits), glycosylated	Induces IFN γ production by T and NK cells, enhances NK and antibody-dependent cell-mediated cytotoxicity, induces T $_H$ 1 subset development
IL-13	17, glycosylated	Inhibits monocyte function, activates B cells
IL-15	14, glycosylated	Activates T and LAK cells and gut epithelium
IL-16	14, functions as a tetramer	Chemoattractant for eosinophils and CD4 $^+$ lymphocytes
IL-17	20, glycosylated	Proinflammatory cytokine
IL-18	18	Enhances NK cytotoxicity, induces IFN γ production
IFN γ	17, glycosylated, functions as a dimer	Induces MHC class I and II, upregulates antigen presentation, macrophage activator, antiviral, antiproliferative, inhibits T $_H$ 2 responses

homologous binding domains, but nonhomologous cytoplasmic domains, suggesting a different mechanism of signal transduction, and probably different functions.

Cytokine receptors appear to have evolved in families. The largest of these is termed the 'hematopoietin' family, and includes the erythropoietin receptor, IL-2R p75 (β chain), and receptors for GM-CSF, IL-3, IL-4 and IL-7, etc. The extracellular domains of these receptors all contain conserved cysteines, as well as a Trp-Ser-X-Trp-Ser motif near to the transmembrane region. The two TNF receptors, nerve growth factor receptors and lymphocyte surface antigens (CD27, CD30, CD40 and OX40 Fas) belong to another family. The extracellular region of these molecules contain a number of repeated cysteine-rich 40 amino acid domains.

How is cytokine action controlled?

Since cytokines have such potent effects, it is clearly important that their action be limited to avoid the pathogenic effects of cytokine overdose. This subject is only beginning to be understood. For IL-1 there is a receptor antagonist which interferes with IL-1 binding to its receptors, but by far the most common inhibitors of cytokines appear to be truncated forms of the extracellular domain of the receptors. Such molecules have been demonstrated for IL-1 (type II), IL-2 (p55), IL-4, IL-7, TNF-R (both chains) and IFN γ , and are not limited to cytokines; similar molecules are also found for hormones, e.g. growth hormone receptor and IGF-1 receptor and adhesion molecules. There is also a soluble extracellular domain of the IL-6 receptor, but it is costimulatory as

opposed to inhibitory. The current concept is that circulating cytokine inhibitors prevent small concentrations of cytokines from exerting prolonged or diffuse effects. It is likely that the balance of cytokine-to-cytokine inhibitor will be of paramount importance in determining whether cytokines exert physiological or pathological effects. There is now clear-cut evidence that excess TNF α signaling is involved in the pathogenesis of rheumatoid arthritis.

Summary

Table 1 summarizes the main properties of the best known cytokines.

CYTOMEGALOVIRUS, INFECTION AND IMMUNITY

PD Griffiths, Department of Virology, Royal Free Hospital School of Medicine, London, UK

Cytomegalovirus (CMV) is a common infection which usually only causes damage if the host immune response is immature or compromised. It is thus an important pathogen to the fetus, to allograft recipients and to those with the acquired immune deficiency syndrome (AIDS).

Characteristics of the organism and its antigens

Cytomegalovirus is a typical herpesvirus. It contains double-stranded DNA of 2.4×10^5 base pairs which makes it the largest virus known to infect humans in terms of genome size. The proteins are expressed in an infected cell in an ordered cascade sequence termed α (immediate early), β (early) or γ (late). Typically, they function as regulators of cell metabolism, enzymes and structural proteins of the virus, respectively. Many of the primary translation products are modified by glycosylation, cleavage or phosphorylation. Chee and colleagues have analyzed the complete sequence of one strain of CMV which encodes approximately 202 proteins. Recently, an additional 22 open reading frames have been

described in one or both of two further strains of CMV.

Approximately 25% of the total open reading frames can be assigned functions, with many more having sequence homologies to known proteins. The surface structures which may be important for immunity exist as high molecular weight glycoprotein complexes which have been termed gCI, gCII and gCIII. The gCI complexes have also been termed gB because they have homology with herpes simplex virus (HSV) glycoprotein B, while the gCIII complexes are called gH. Like HSV, the gH of CMV requires gL for its expression.

A characteristic feature of the virus is its ability to establish latency for the life of the individual. There are probably multiple sites the virus can reactivate from at multiple occasions. It often does so when the patient is otherwise debilitated, i.e. CMV acts as an opportunist.

Immune responses of the host

Cell-mediated immunity

Cytotoxic T lymphocytes are predominantly directed

against structural phosphoproteins of the virus which are revealed immediately CMV enters the cell. It can be inferred that cell mediated immunity (CMI) is the major means of controlling CMV replication, as CMV is a major pathogen in groups of patients whose CMI responses are depressed. In the murine model of CMV, natural killer cells have also been shown to be important. Genetic investigations have mapped susceptibility to infection to the class I loci of the major histocompatibility complex (MHC), which probably represents an immunologic phenomenon rather than a receptor interaction as postulated in the past.

Humoral immunity

Some of the humoral responses to viral proteins can be documented by western blot or immunoprecipitation. Two surface glycoproteins, gB and gH, have so far been shown to have neutralizing domains.

Note that the combined humoral and CMI responses of the host are not sufficient to prevent reactivation of latent virus nor to protect against reinfection from exogenous sources. However, there is increasing evidence that humoral immunity may ameliorate disease.

Immunopathology

There is considerable evidence from both mice and humans to suggest that CMV pneumonitis is an immunopathologic condition. In addition, CMV is associated with infection of solid organ grafts and with graft-versus-host disease after bone marrow transplantation. One possibly causal mechanism is that CMV upregulates adhesion molecules.

Evasive strategies by the organism

1. Latency. This probably allows no or very minimal expression of virion proteins which could be presented as peptides in the context of MHC class I molecules. The cell with latent CMV genome would therefore be undetectable by circulating cytotoxic T cells.
2. The virus can spread by cell-to-cell fusion, so avoiding an extracellular phase where it may be susceptible to neutralization by antibody.
3. Murine and human CMVs decrease surface display of mature HLA complexes as a final common pathway for avoiding cytotoxic T lymphocyte (CTL) recognition. The methods are complex and multiple. For human CMV, these include the input UL83 (pp65) protein phosphorylating the major immediate-early protein and so preventing its presentation. At

immediate-early times, the US3 gene product retains Class I molecules in the endoplasmic reticulum (ER). At early times, gene products US2 and US11 re-import Class I molecules from the ER back into the cytosol where they are degraded. At early/late times, gene product US6 blocks peptide transport into the ER. At late times, gene UL18 (which encodes a Class I-like protein) is displayed to decoy NK cells which would otherwise destroy a cell lacking Class I molecules.

4. CMV is generally accepted to cause 'immunosuppression' in clinical practice and is associated with bacterial or fungal infections. While the mechanism(s) remain undefined, this may decrease the host's ability to control CMV infection.

Vaccines

One live attenuated vaccine strain (Towne) was subjected to a well-conducted placebo-controlled trial carried out by Brayman and colleagues. Unfortunately, the vaccine had no effect on the incidence of CMV infection or CMV disease, although the severity of disease was reduced. Due to the theoretical risks of the DNA from this virus containing transforming regions, further studies with this vaccine outside high-risk populations are unlikely.

A recombinant gB vaccine has proceeded to phase I clinical trials and is well tolerated. Seronegative volunteers seroconverted and seropositive volunteers had significant increases in antibody levels. The vaccine may be tested in transplant patients and may be used to immunize normal blood donors to produce specific immunoglobulin.

There is evidence for adoptive transfer of immunity following bone marrow transplantation from immune donors. CD8⁺ CTL clones isolated from the marrow donor can be reinfused safely into bone marrow recipients and may provide protection against CMV disease in the critical early weeks after transplantation.

CYTOTOXIC T LYMPHOCYTES

Vivian Lam Braciale, Department of Microbiology, The Beirne Carter Center for Immunology Research, University of Virginia, Charlottesville, Virginia, USA

Cytotoxic T lymphocytes (CTLs) are a functional subset of the cellular arm of antigen-specific immune responses. They play a major role in protection and recovery from viral infection, mediate allograft rejection, are implicated in certain autoimmune diseases, contribute to protection and recovery from certain bacterial and parasitic infections, and to tumor immunity. Our understanding of CTLs has evolved from their characterization as solely CD8⁺, class I major histocompatibility complex (MHC)-restricted, nonproliferative endstage effectors, to T cells that can employ one or several mechanisms of cytolytic activity (perforin/granzyme, FasL/Fas, tumor necrosis factor α (TNF α)), produce different subsets of lymphokines (CD4⁺ T_H1, CD4⁺ T_H2), and recognize foreign antigen in the context of either class I or class II MHC molecules (CD8⁺CTL, CD4⁺CTL, respectively).

Historical perspective

The effector cells in cell-mediated immunity which demonstrate specific cytotoxic activity as described by Govaerts in 1960 are cytotoxic T cells (also called cytolytic T lymphocytes, killer T cells, and abbreviated as CTLs). Some of the major questions involving cytotoxic T cells in the past included the nature of MHC restriction, the nature of the T cell receptor and diversity of the T cell repertoire, the enigma of alloreactivity and Mls reactivity and learning of self MHC in the thymus. Zinkernagel and Doherty in 1974 (working with CTLs specific for a lymphocytic choriomeningitis virus (LCMV)), and independently, Shearer and colleagues in 1975 (working with MHC-restricted responses specific for hapten (TNP)-modified spleen cells), extended the phenomenon of MHC-restricted recognition by T cells to CTLs. At that time, in the absence of biochemical and structural information on the T cell receptor, the two prevailing hypotheses were that 1) there were two separate receptors, one for the foreign antigen and one for self MHC (the restriction molecule) or 2) a single receptor could recognize an altered self MHC determinant. It is now known that the T cell receptor is comprised of an $\alpha\beta$ heterodimer coexpressed with several nonpolymorphic chains (CD3) which exhibits both the foreign antigen specificity and the MHC-restriction specificity. The 'altered-self' MHC molecule is now known to be an MHC molecule which

binds and presents a fragment of antigen to the T cell.

Also at question at that time was how diverse is the T cell repertoire since there are CTLs with exquisite MHC restricted foreign antigen recognition as well as a high frequency of CTLs which recognize allo-MHC molecules independent of self MHC restriction. It was estimated that ~1% of cytolytic T cells recognize a given allogeneic MHC molecule while as many as 20% could recognize Mls loci determinants. The precursor frequency for a given foreign antigen is merely ~1/10 000. Examination of clonal CTL populations revealed that a given T cell could recognize foreign antigen in an MHC-restricted fashion and additionally recognize allo-MHC. This dual specificity was also demonstrated for Mls reactivity. The current view is that alloreactivity may be directed to allo-MHC molecules which bind and present self peptides.

Nature and characteristics

Classically described cytotoxic T cells are class I MHC-restricted (i.e. foreign antigen is recognized in the context of H2-K, D or L molecules in the murine system and HLA-A, B or C in the human). These effectors also express the cell surface molecules Thy-1, Lyt-1, Lyt-2,3 (CD8), TCR $\alpha\beta$, CD3 and LFA-1. In the 1980s, it was then reported in the human for virus-specific CTLs and subsequently confirmed in the murine model that class II MHC-restricted CTLs are elicited in response to viral antigens. These effectors bear the cell surface molecules Thy-1, Lyt-1, LFA-1, L3T4 (CD4), CD3 and TCR $\alpha\beta$. Concomitant with these reports, the suggestion was independently put forth that Lyt-2 (CD8) and L3T4 (CD4) expression are more clearly correlated with class I and class II MHC restriction, respectively, than with cytotoxic effector and helper functions, respectively. Exceptions to the rule have been found (e.g. Lyt-2⁺ class II MHC-restricted CTLs), but the correlation holds for the bulk of CTLs. The class II MHC-restricted CTLs may have been overlooked in earlier studies because many tumor cell and fibroblast cell lines and macrophages used as target cells did not express class II MHC molecules. Target cells for human CTLs, however, are usually EBV-transformed B lymphoblastoid cell lines (LCL), which generally express class II MHC molecules.

Clonal CTL populations have been mapped for their MHC restriction molecule by comparing lysis of class I MHC-bearing targets with targets which bear both class I and class II MHC molecules (e.g. B lymphoma cells). Transfected murine cell lines where a given class I or class II MHC molecule is expressed in a cell bearing MHC molecules of a different haplotype have proven useful as target cells to map MHC restriction. In the human, homozygous typing lines have been used as targets, but the serological classification of class I and class II MHC molecules does not always help to distinguish restriction molecules recognized by CTLs. Transfected murine fibroblast lines which express human class I or class II MHC molecules have proven useful in these cases. Antibodies directed towards the class I or class II MHC molecules generally inhibit the cytolysis of specific target cells (antibodies directed towards the foreign antigen generally do not inhibit). In addition, antibodies directed to CD8 or CD4 molecules have been shown to inhibit cytolysis by class I MHC-restricted and class II MHC-restricted T cells, respectively. Anti-LFA-1 specific antibodies block cytolysis mediated by either CD8⁺ or CD4⁺ CTLs.

CTL induction and growth

Most MHC-restricted CTL responses directed to viral antigens, tumor antigens, soluble protein and minor histocompatibility antigens require *in vivo* immunization or priming. In the case of strong responses, MHC-restricted, antigen-specific T cells can be obtained by day 7 postimmunization. Upon *in vitro* secondary restimulation with limiting numbers of primed precursors one can obtain clonal CTL populations. In general, class I MHC-restricted CTLs require an exogenous source of T cell growth factor, interleukin 2 (IL-2), in addition to the antigenic stimulus, while class II MHC-restricted CTLs do not. If cloned in the absence of exogenous IL-2 and at a high precursor density per well, rare CD8⁺, class I MHC-restricted CTLs which produce IL-2 can be selected. CTL antigen specificity and MHC restriction can also be determined in proliferation assays. At one time, cytotoxic T cell effectors were considered to be end-stage cells incapable of proliferating (much like antibody-secreting plasma cells). It has been shown, however, that CTLs can continue to proliferate but only upon specific antigenic stimulation. Some general features of CTL induction are depicted in **Figure 1**. The events are the same for both class I MHC-restricted CD8⁺ CTLs and class II MHC-restricted CD4⁺ CTLs. The first signal in the activation of precursor CTL (pCTL) is the antigen/MHC complex recognized by the pCTL T

cell receptor (TCR). The costimulatory (or second) signal once considered to be IL-1 (soluble or membrane-bound) for CD4⁺ pCTL, is now thought to be B7(CD80), the ligand for CD28 expressed on the pCTL. The activated T cells undergo RNA synthesis, protein synthesis and expression of IL-2 receptor α (IL-2R α) resulting in expression of high-affinity IL-2 receptors (IL-2R $\alpha\beta\gamma$). Upon engagement of IL-2 by IL-2R the T cell blasts undergo DNA synthesis and subsequent cell division. Whether an additional cytotoxic differentiation factor (CDF), such as IL-12, is required at this time to allow the T cells to gain cytolytic effector function remains to be demonstrated. Whether mature CTLs and memory CTLs are one and the same also is not known. These mature/memory CTL eventually downregulate IL-2R α expression and stop proliferating until they receive an antigenic stimulus once again.

Also depicted in **Figure 1** the current scheme that there are two predominant pathways of antigen presentation, one for class I MHC-restricted recognition and the other for class II MHC-restricted recognition. Crossover between the two pathways have been described to occur. For the most part, however, antigen synthesized endogenously within the antigen-presenting cell or target cell (or somehow introduced into the cell cytoplasm) can be processed and presented in the context of class I MHC molecules. Antigens which are taken up by an endocytic route by the antigen-presenting cell or target cell are processed and presented in the context of class II MHC molecules. As a result of this distinction, infectious virus can elicit both class I and class II MHC-restricted CTLs *in vivo* while inactivated virions generally elicit just class II MHC-restricted T cells *in vivo*.

Mechanisms of cytolysis

Recent advances in studies of the mechanism of CTL cytolytic effector function have resolved a long-standing controversy. Two opposing hypotheses, the cytolytic granule exocytosis mechanism and the calcium-independent, perforin-independent mechanism are now known to be independent or overlapping but not mutually exclusive mechanisms. The granule exocytosis hypothesis describes the cytolytic event as resulting from a calcium-dependent secretion of cytoplasmic granules into the extracellular space bounded by the cytotoxic T cell membrane/target membrane junction. The perforin inserts into the target cell membrane and forms pores through which granzymes are introduced into the target cell allowing for events that result in target cell apoptosis and nuclear DNA fragmentation. In 1993, the mechanism of Fas ligand/Fas-mediated cytolysis

Figure 1 Induction of CD8⁺ and CD4⁺ cytotoxic T lymphocytes.

was described which accounts for the previously described calcium-independent, perforin-independent cytolytic mechanism. Fas (CD95) is a member of the tumor necrosis factor receptor family (TNFR) expressed on the target cell and while FasL (CD95L) is a member of the tumor necrosis factor (TNF) family expressed by CTL upon antigen-specific activation. CTL can mediate cytolysis of target cells by FasL/Fas-mediated cytolysis and/or by exocytosis of cytolytic granules containing perforin/granzymes in short-term *in vitro* assays. Thus, calcium-independent cytolysis can be achieved by CTLs that lack perforin-containing granules, via the FasL/Fas mechanism. This form of cytolytic effector function remains intact in mice that are deficient in perforin. Thus far, there are CD8⁺ CTLs that employ both the perforin/granzyme and FasL/Fas mechanisms of cytolysis (**Figure 2**) and CD8⁺ CTLs that employ the FasL/Fas mechanism only. In a mutant strain of mice, *gld*, the T cells express defective FasL and thus are defective in FasL/Fas lysis. CD4⁺ CTLs employing both mechanisms of cytolysis have been reported for viral-specific T cells (**Figure**

2) and CD4⁺ CTLs that employ solely the FasL/Fas mechanism have been reported for alloreactive CTL. In addition to these CD4⁺ CTLs, which are generally of the T_H1 subset, viral-specific CD4⁺ T_H2 cells have been reported to demonstrate FasL/Fas cytolytic activity. CD4⁺ (**Figure 2**) T_H1 cells produce IL-2 and interferon γ (IFN γ) while CD4⁺ T_H2 cells produce IL-4 and IL-5. Although not as systematically characterized *in vitro*, it is believed that most of these CTLs can mediate cytolysis via membrane-bound or soluble TNF α *in vitro* and *in vivo*. TNF α -mediated lysis of target cells is not detectable in the classical short-term cytotoxicity assays. Another feature of TNF α and FasL/Fas lysis is that the target cells must express TNFR or Fas respectively, whereas perforin/granzyme cytolysis requires only the specific Ag/MHC complex to be presented.

Lysis mediated by CTL is generally quantitated using the classic ⁵¹Cr-release assays developed in 1968 by Brunner and colleagues where lysed cells release ⁵¹Cr into the medium. Target cell DNA fragmentation which occurs before cell lysis can be detected using a modified ¹²⁵IUDR assay (Russell and

Figure 2 Perforin/granzyme granule exocytosis and FasL/Fas cytotoxicity mediated by CD8⁺ and CD4⁺ CTLs.

Dubos) using nonionic detergent to dissolve the target cell membranes. The lytic activity by particular cytotoxic T cell populations can be compared with that of another population by comparing lytic units. A lytic unit (LU) is the number of effectors required to achieve an arbitrary amount of lysis (e.g. 50%) in a particular amount of time (e.g. 4 h) using data derived from a range of effector-to-target ratios. Events in cytotoxicity generally fall into three stages termed 1) conjugate formation or adherence, 2) lethal hit delivery, and 3) target cell lysis or disintegration. A detailed discussion of these stages can be found elsewhere (see Mechanisms of cytotoxicity above). Both specific and nonspecific conjugates can form between T cells and target cells in the presence of Mg^{2+} via LFA-1 and its coreceptor ICAM-1, CD2 and its coreceptor LFA-3. For perforin/granzyme cytotoxicity, the lethal hit delivery is both temperature and calcium dependent. Target cell disintegration can occur in the absence of the CTL following the lethal hit. CTLs can recycle, i.e. kill more than one target cell. *De novo* protein synthesis is not required for perforin-mediated cytotoxicity as the perforin exists

in preformed granules, but it is required for FasL expression. A hallmark of short-term CTL assays (4–6 h), is that there is no bystander killing of nearby nonspecific target cells. T cell-mediated cytotoxicity is unidirectional killing in that CTLs are spared the lethal hit delivery by some unknown mechanism.

Cytoplasmic granules in CTLs contain perforin (or cytolyisin) and members of a family of serine esterases (granzymes). Secretion of granzyme A activity into the medium following cytotoxic T cell/target cell interaction has been used as an assay of granule exocytosis but not necessarily cytotoxicity. There is clonal variation with regard to granzyme A content and mice genetically manipulated to be granzyme A deficient retain cytotoxic activity while mice rendered granzyme B deficient are deficient in cytotoxic T cells.

Cytokines reported to be released following killer target cell interaction are IFN- γ and lymphotoxin (LT) in addition to the previously mentioned TNF- α . The *in vivo* release and function of these cytokines are under investigation. It is unlikely that they play a direct role in short term *in vitro* cytotoxicity since there is little bystander killing and cytotoxic activity is not

demonstrable in supernatants of killer T cells cocultured with specific target cells.

In vivo function

As mentioned above, cytotoxic T cells have been shown to effect allograft rejection, mediate autoimmune tissue damage, and protect against and promote recovery from viral and bacterial infections. CTLs with viral specificity have been shown to lyse virus-infected target cells before virus budding and sometimes before viral genome replication. This serves to limit the release of virus particles and also limit cell-to-cell spread of virus. Perforin-deficient mice are unable to efficiently clear virus in infected animals yet are able to reject allografts. This points to a differential use of cytolytic effector function. It has been suggested that perforin-mediated cytolysis may be employed to control spread of infectious pathogens while FasL/Fas-mediated cytolysis as well as TNF α -mediated cytolysis may be involved in immunoregulatory events that limit lymphoproliferation and dysregulated autoimmune responses.

Methods to manipulate CTL populations have included vaccine designs to elicit *in vivo* class I MHC restricted as well as class II MHC restricted CTL responses as well as introduction of *in vitro* manipulated CTL populations. When cloned CTLs with influenza virus specificity and class I or class II MHC restriction were adoptively transferred into mice given an intranasal dose of influenza virus, the lung viral titers were 100-fold lower and the mice recovered while the infected group that did not receive the T cell clones died within one week. Other *in vivo* studies indicate that there is little or no bystander killing *in vivo*. Since *in vitro* cultured CTLs can demonstrate *in vivo* function, studies are underway in a number of model systems to elicit CTLs to tumors and viral antigens, propagate these effectors *in vitro* and transfer them back *in vivo*. Progress on this front has been reported for cytomegalovirus-specific CTL transfer into bone marrow transplant patients and experimental protocols to introduce *in vitro* expanded human immunodeficiency virus (HIV)-specific CTLs in patients with the acquired immune deficiency syndrome (AIDS) are currently under development.

CYTOTOXICITY, ASSAYS FOR

Nobukata Shinohara, Mitsubishi-Kasei Institute of Life Science, Tokyo, Japan

A variety of immunological effectors attack cells, resulting in cytolysis of the targets. These include specific antibody with complement, cytotoxic T lymphocytes (CTLs), natural killer (NK) cells, lymphokine-activated killer (LAK) cells, the effectors of antibody-dependent cellular cytotoxicity (ADCC), macrophages, neutrophils and certain substances secreted by cells such as tumor necrosis factor (TNF) and perforin. CTLs and NK cells are known to utilize dual pathways of cytotoxic machinery: perforin + granzyme mediated and Fas ligand mediated. Cell death is generally categorized into two different types. One, called programmed cell death (apoptosis), involves active metabolic process of the dying cell resulting in disintegration of nuclear DNA and an increase in the permeability of the cell membrane. The other type, called necrosis, does not involve active metabolic process and results in an increase in membrane permeability without immediate nuclear disintegration. Cell-mediated cell lysis generally induces the former type of cell death, whereas cell lysis mediated by antibody and complement causes

the latter type. Accordingly, there are two different principles for detecting cell death: one for measurement of increased membrane permeability and the other for detecting DNA disintegration.

Two types of methods for monitoring membrane permeability of cells are widely used as cytotoxicity assays. One is the dye exclusion test. This assay involves microscopical counting of dead cells stained with a dye, such as trypan blue, to which viable cell membrane is impermeable. These agents, because of their basic nature, stain cell nuclei when they have entered the cells across the damaged cell membrane. By this method, the percentage of dead cells can be directly determined. The other method is the chromium-release assay, in which target cells are labeled with radioactive ^{51}Cr . When cultured in the presence of a trace amount of $\text{Na}_2^{51}\text{CrO}_4$, viable cells take up Cr^{6+} . Once inside the cell, the Cr^{6+} is reduced to Cr^{3+} . The Cr^{3+} binds to multivalent anions, including proteins present in the cells. This results in the formation of molecular complexes which are not easily released from cells unless the

Figure 1 Two types of cytotoxicity assay. In the Cr-release assay, an increase in membrane permeability is measured. In the IUdR-release assay, disintegration of nuclear DNA is measured.

cell membrane is damaged. Thus, cell death can be determined by measuring radioactivity released from dead cells into the supernatant (**Figure 1**). Results are usually expressed as specific Cr release (%) calculated according to the following formula:

$$\frac{(\text{experimental release}) - (\text{spontaneous release})}{(\text{maximum release}) - (\text{spontaneous release})} \times 100,$$

where spontaneous release is the background radioactivity released in the absence of the effector and maximum release is the amount of released radioactivity when the target cells are maximally lysed by acid or detergent. The specific Cr release does not faithfully represent the actual percent of dead cells. This is because the efficiency of Cr uptake and spontaneous release of Cr can significantly vary from cell to cell in a heterogeneous cell population, and the maximum release induced by detergent is, for unknown reasons, usually significantly (approximately 20% on average) higher than Cr release when 100% of the cells are lysed by the effector. In order to quantitate the lytic activity of the effector, titration of the effector activity is necessary. Determination of lytic activity at a single effector: target ratio does not give an accurate estimate of cytotoxicity, as a small difference in the values of specific Cr release (less than 10%) is not reliable. Furthermore, above the plateau (79–80%), differences cannot be detected. Generally, the Cr release assay is used for cell-mediated target cell lysis because the presence of an excessive number of effector (or attacker) cells becomes problematic when using the dye exclusion assay. Furthermore, because of the ease of quantitation, this assay is favored when a large number of samples is involved.

For quantitative measurement of DNA disintegration, labeling nuclear DNA with ^{125}I UdR or ^3H -thymidine is widely used. Since labeling nuclear DNA depends on cellular synthesis of DNA, this method is applicable only for rapidly dividing cells such as tumor cells or blast cells. When a dividing population of cells are cultured in the presence of ^{125}I UdR for 1–2 hours, a portion of cells incorporate the label into newly synthesized DNA strands. The

chromosomal DNA remains in the nuclear matrix even after lysing cells with detergent. When nuclear DNA fragmentation takes place, small DNA fragments become released from the nucleus. In the assay, after incubation with the effectors, the whole cell mixtures are lysed with detergent and radioactivity in the supernatant is measured after pelleting nuclei by centrifugation. DNA fragmentation is usually expressed as percentage of specific IUDR release, which is calculated in a similar manner as the above-mentioned Cr release.

CYTOTOXICITY, MECHANISMS OF

Pierre Golstein, Centre d'Immunologie INSERM-CNRS de Marseille-Luminy, Marseille, France

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In 1960 Govaerts showed that white peripheral blood cells from alloimmune dogs were able to lyse *in vitro* target cells bearing the corresponding allo-antigens. Four decades and several thousands of publications later, we know that many different cell types have this ability to destroy other cells. This entry is concerned, however, essentially with lymphoid cells (thus not touching in detail upon mechanisms of cytotoxicity by activated macrophages or by polymorphs, for instance). Among lymphoid cells, we consider mostly cytotoxic T lymphocytes. We briefly review, first their *in vivo* roles, then the phenomenology of cytotoxicity, and finally molecular studies leading to the identification of two main mechanisms of T cell-mediated cytotoxicity as assessed in short-term *in vitro* assays, namely a mechanism involving granule exocytosis, perforin and granzymes, and a mechanism involving Fas and its ligand.

Why do cytotoxic cells exist at all? Under physiologic circumstances (i.e. not for instance in a situation of allograft rejection), they can meet and destroy only syngeneic cells. Since cells from a given organism usually cooperate rather than destroy each other, the selective advantage overriding this rule must be considerable. It is now believed that a main role of cytotoxic T cells is to lyse syngeneic cells presenting surface determinants originating from viruses or other intracellular microorganisms. These, when within cells, are out of reach of other immune system effectors. Destruction of infected cells destroys the microorganism or exposes it to other effector mechanisms. A teleological justification for the existence of T cell-mediated cytotoxicity, perhaps in particular perforin based, thus seems to be its role in fighting intracellular pathogens. Another *in vivo* counterpart, of in particular Fas-based cytotoxicity, is downregulation of immune responses, in part through recognition and destruction of Fas-bearing activated lymphocytes. Neither the perforin- nor the Fas-based mechanisms in isolation, nor both together, seem to fully account for graft rejection. A possible role in spontaneous clinically significant tumor cell rejection is not clear; the therapeutic use against established tumors and their metastases of cytotoxic lymphokine-activated killer (LAK) cells or intratumor-derived cytolytic cells is still being investigated.

Another intriguing possibility, stemming from the finding that cytotoxic T cells recognize at the surface of target cells peptides which may derive from any

protein (even intracellular), has been raised in particular by Thierry Boon's group in Brussels. A cell in which a given protein has been modified by somatic mutation would present at its surface correspondingly modified peptides. These would be recognized as foreign by the immune system. Activated cytotoxic T cells may consequently destroy the mutation-bearing cells. An important role of cytotoxic T cells might thus be to 'proofread' the genome against somatic modifications.

Phenomenological studies

How do cytolytic cells destroy target cells? This has been studied in a very analytical, very reductionist manner in model systems *in vitro*. A large variety of techniques have been used, while cytotoxicity itself has been most frequently assessed using the ^{51}Cr -release assay introduced in this field by T. Brunner and colleagues in Lausanne. Briefly, target cells are labeled by incubation with radioactive chromate, then washed of unincorporated label. Addition of cytotoxic cells induces lysis of target cells, and therefore release of intracellular chromium-labeled molecules. The percentage of radioactivity released in the supernate reflects the percentage of lysed target cells and thus indirectly the lytic efficiency of the cytotoxic cells under test. Studies on the mechanisms of cytotoxicity include phenomenological descriptions, some of which date back a number of years, and more recent molecular investigations.

Phenomenological studies concurred to provide a minimal description, a basic scenario of the lysis of a target cell by a cytotoxic T cell. The first stage of lysis is recognition, which involves an array of diverse molecules at the surface of the effector cell (such as TCR/CD3/peptide, CD4 or CD8, LFA-1 . . .) and of the target cell (class I or class II MHC, ICAM-1 . . .).

Engagement of these molecules triggers a remarkable succession of events in the effector cell. An early sign, and a further trigger, of lymphocyte activation is the increase of free cytoplasmic calcium, shown by Poenie *et al* in Berkeley in 1987 and by other groups, using real-time video an intracellular probes the fluorescence of which varies as a function of calcium concentration. This increase occurs in a matter of minutes and is immediately followed by reorientation, within the effector cell, of the secretory apparatus towards an area facing the target cell, as

shown in particular by S.J. Singer and his colleagues in California in 1985. This suggested the possible participation of secretory phenomena in cytotoxicity. Many cytotoxic T cells indeed contain peculiar cytoplasmic granules. Their content can be released by degranulation in the extracellular fluid upon target cell recognition. Interestingly, reorientation of the secretory apparatus is calcium dependent, and so usually are degranulation systems.

Among the phenomena then observed in the target cell, a calcium influx resulting in a very high cytoplasmic calcium concentration is prominent. Also very striking is the early disintegration of nuclear DNA, first observed in this system by J. Russell (St. Louis). Disintegration of DNA into fragments of around 180 bp, and multiples thereof, corresponding to the size of nucleosome-shielded DNA, is very likely due to the action of one or several endonucleases activated early in the sequence of events leading to target cell death. Other events in this sequence include cytoplasmic condensation, cytoplasmic and nuclear fragmentation, and only very late secondary membrane disruption.

This schematic description leads to three remarks. First, there are several calcium-dependent events in the process described above. Indeed, T cell-mediated cytotoxicity is mostly calcium dependent at the population level. However, some cytotoxicity does occur in the absence of extracellular calcium within alloimmune *in vivo* or *in vitro* raised cell populations, and some clones could be shown to exert considerable levels of cytotoxicity under these conditions. This led in the late 1980s to the speculation that at least two distinct cytotoxic mechanisms may exist, depending or not on extracellular calcium, in the same cells or in different cells.

The second remark bears on the fact that once a cytotoxic T cell has lysed a target cell, it can proceed to lyse another one. Thus, it is clearly itself not permanently affected by the killing process. For the target cell to be lysed without destroying the effector cell, the killing mechanism should be polarized, unidirectional from the effector cell towards the target cell. Alternatively, the killing mechanism may not be polarized (it may for instance include a soluble extracellular substance), but then the killer cell should be resistant to it, and therefore to other killer cells. Experiments testing whether cytotoxic T cells could be lysed by other cytotoxic T cells were performed at the population level and also more recently at the clonal level. The conclusion seemed to be that although cytotoxic cells can indeed be sensitive to some cytotoxic cells, some are resistant to others and particularly to themselves. However, these experiments did not take into consideration the then

unknown fact that two distinct cytotoxicity mechanisms were at play, and the nature of these mechanisms. Resistance/sensitivity of cytotoxic T cells to cytotoxicity mechanisms should be reinvestigated accordingly.

The third remark is that the phenomenology of cell death is very similar, if not identical, whether death is induced by cytotoxic cells or occurs, say, in developmental circumstances. In both cases, the same program seems to govern the course of events in a cell that dies, including as we now know a similar cascade of molecular events, and the same 'apoptotic' morphologic traits described by John Kerr *et al* in 1972. What may be different is merely the signaling of this death program. The nature of the signals produced by cytotoxic cells has been largely unraveled by studies at the molecular level.

Molecular studies

A first approach to the identification of molecules involved in cytotoxicity has been, naturally enough, to look for molecules themselves endowed with cytotoxic activity, and present either in the supernates of cytotoxic cells, or in subcellular fractions of these. This approach, among others, contributed to the identification, and later the cloning, of tumor necrosis factor (TNF- α) and lymphotoxin (TNF β). Using the corresponding antibodies, TNF α , probably in a membrane-bound form, has been shown to be required for cytolysis mediated by natural cytotoxic (NC) cells, by some activated macrophages, and more recently by activated T cells in long-term cytotoxicity tests *in vitro*.

This approach also led to the detection (initially by P. Henkart *et al* and by E. Podack *et al*, in 1983–1985), the characterization and the cloning of perforin. Perforin is a 60 kDa molecule present in granules in the cytoplasm of many cytotoxic T and natural killer (NK) cells; at high concentrations, it can act on membranes as a calcium-dependent channel-former; most interestingly, it shows significant homology to the terminal components of the complement cascade. A formal demonstration that perforin was involved in a mechanism of cytotoxicity was provided by Kägi *et al* in 1994, followed by several other groups, all showing that cytotoxicity mediated by T cells was greatly impaired in mice made perforin deficient through gene targeting.

Other molecules present in granules of cytotoxic T cells were identified by subtractive hybridization cloning techniques. Prominent among molecules isolated this way were a number of serine esterases, such as CTLA-1 (Brunet *et al* 1986, also isolated by Lobe *et al* under the name CCP1 and by Tschopp *et*

al under the name granzyme B) and CTLA-3 (Brunet *et al* 1986, also isolated by Gerschenfeld and Weissman under the name H Factor and by Tschopp *et al* under the name granzyme A). Heusel *et al* demonstrated in 1994, also using gene-targeted mice, that granzyme B is required in a mechanism of cytotoxicity. It would seem that, upon recognition of the target cell, in the effector cell perforin- and granzyme B-containing granules reorient towards the target cell and are triggered to exocytose. In a still unclear manner, perforin would then facilitate the entry of, in particular, granzyme B into the target cell, where it may trigger the programmed cell death cascade by activating members of the ICE family of cysteine proteases.

Meanwhile, a somatic cell genetic approach led Rouvier *et al* in 1993 to the finding that another mechanism of T cell-mediated cytotoxicity required Fas (otherwise called APO-1 or CD95) at the target cell surface. This in turn led to the cloning by Suda *et al* of the Fas ligand, expressed at the effector cell surface. These molecules belong, respectively, to a family of receptors (including Fas, the TNF-Rs, CD30, CD40 . . .; most or all being very efficient at transducing a signal interpreted as a cell death or cell survival signal) and to a family of ligands (including the Fas ligand, the TNFs, the CD30 and CD40 ligands . . .). Involvement of Fas in cytotoxicity may be a reflection *in vitro* of a main role *in vivo* of downregulation of the immune response.

While triggering of cell death in development involves largely unknown signals, the Fas pathway is one of the very few programmed cell death pathways in higher eukaryotes in which signaling is in part molecularly defined. Signaling in the Fas pathway runs in the effector cell from TCR engagement (by target cell MHC) to expression of the Fas ligand, then in the target cell from engagement of Fas (by effector cell Fas ligand) to death. It therefore is a two-cell twice-*trans* process.

The residual cytotoxicity of *in vitro* and *in vivo* induced cytotoxic T cells from perforin-deficient mice seemed exclusively Fas-based, in several systems, as shown by Kägi *et al* in 1994 and by others. In many experimental situations only perforin- and Fas-based cytotoxicity mechanisms could be detected. These two mechanisms thus seem to account for all of the classical cytotoxic T lymphocyte phenomenology, in short-term (i.e. 4 h) cytotoxicity tests *in vitro*. The Fas pathway is used by both CD4⁺ (mostly T_H1) and CD8⁺ effector cells, while the latter also use the perforin/granzyme pathway. Thus, in CD8⁺ T cells, two signals may stem from the TCR/CD3 complex upon antigen-specific recognition, one of them leading to granule exocytosis

and the other one leading to transcription of the Fas ligand gene. Neither the exact nature of these signals nor whether they can be triggered simultaneously in a given cytotoxic cell is known as yet.

More generally, both mechanisms of T cell-mediated cytotoxicity may act by signaling intermediate steps of a conserved programmed cell death cascade within the target cell. This speculation is based, for the Fas pathway, on weak homologies between the death domains (of Fas and TNF-R1) and the death-signaling molecule reaper in *Drosophila*, and for the perforin pathway on recent findings that granzyme B can activate at least one of the ICE family members. In this sense, the emergence in evolution of T cell-mediated cytotoxicity may have required the invention, not of new mechanisms of killing, but merely of new ways of signaling a pre-existing programmed cell death cascade.

Conclusion

How T cells are able to kill other cells is no more a complete mystery. As assessed by short-term cytotoxicity tests *in vitro*, they seem to use two distinct mechanisms, perforin/granzyme-based and Fas-based, respectively. These seem to be *in vitro* correlates of, in particular, *in vivo* defense mechanisms against intracellular pathogens and downregulatory reactions within the immune system, while they do not seem to account entirely for graft rejection.

D

DECAY-ACCELERATING FACTOR (CD55)

Taroh Kinoshita, Department of Immunoregulation, Research Institute for Microbial Diseases, Osaka University, Osaka, Japan

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Decay-accelerating factor (DAF), also termed CD55, is a glycoprotein of 65–70 kDa expressed on the surface of all blood cells, vascular endothelial cells and various other tissue cells. It is one of the membrane-bound complement inhibitors that protect host cells from the destructive action of autologous complement. An inherent characteristic of complement is that its active fragments or their complexes can bind to host cell surfaces accidentally or physiologically. This potentially harmful characteristic is prevented by widely distributed membrane-bound complement inhibitors, such as DAF, membrane cofactor protein (MCP or CD46; a 45–70 kDa cofactor for the C3b/C4b-cleaving enzyme factor I) and CD59 (an 18 kDa inhibitor of the membrane attack complex; also termed MACIF, HRF20 or MIRL). A primary function of DAF is to inhibit C3 convertases (C4b2a and C3bBb) and C5 convertases (C4b2a3b and C3bBb3b) on the cell surface; DAF interacts with the convertases and destabilizes them by inducing rapid dissociation of a catalytic subunit C2a or Bb. The inhibitory action of DAF is restricted to C3/C5 convertases bound directly to host cells; that is, DAF does not inhibit normal complement activation on targets, such as microorganisms and immune complexes.

The peptide portion of DAF consists of four tandem repeats of about 60 amino acids, called short consensus repeats (SCRs), followed by a Ser/Thr-rich region of about 70 amino acids. The SCRs are present in 14 complement proteins that bind to C3, C4 or C5 and in other noncomplement proteins. The Ser/Thr-rich region contains multiple O-glycosylation sites. One N-glycosylation occurs in SCRs. A glycolipid anchor covalently linked to the C-terminus of the peptide attaches the protein to the membrane. The glycolipid anchor consists of ethanolamine, which connects the anchor to the peptide, and three mannose residues, glucosamine and phosphatidylinositol, which is attached to the membrane. This glycolipid structure, called glycosylphosphatidylinositol, is a membrane anchor in 100 or more mem-

brane proteins, such as alkaline phosphatase, acetylcholinesterase, Thy-1, the variant surface glycoprotein of *Trypanosoma brucei* and CD59.

In a soluble form, DAF is present in urine, plasma, tears and saliva. Soluble DAF may be released from membrane DAF by the action of phospholipase C or D, or a protease. Soluble DAF has about 100-fold less activity than membrane DAF on cell-bound C3 convertases, and its physiologic function is unknown.

The DAF gene is located in chromosome 1 in band q32 within a cluster of genes of complement regulatory proteins that include SCRs; i.e. factor H, C4-binding protein, MCP, complement receptor 1 (CR1) and 2 (CR2). DAF bears Cromer blood group antigens. Rare individuals called Inab or IFC-lacking Cromer-related antigens are deficient in DAF.

Blood cells of patients with an acquired hemolytic anemia, paroxysmal nocturnal hemoglobinuria (PNH), are deficient in DAF. In the clonal disorder, PNH, abnormal totipotent or pluripotent hematopoietic stem cells give rise to abnormal blood cells showing deficient surface expression of glycosylphosphatidylinositol-anchored membrane proteins. Because of this surface deficiency of DAF and CD59, in PNH a fraction of the red cells is susceptible to complement, resulting in intravascular hemolysis and hemoglobinuria.

DAF acts as a receptor for some microorganisms. Echoviruses of various serotypes, including 6, 7, 11, 12, 20 and 21 and coxsackieviruses B1, B3 and B5, use DAF as a receptor for cell attachment. Uropathogenic *Escherichia coli* binds to cell surface DAF with its fimbriae-like adhesin.

Mouse DAF, which inhibits C3 convertases, has been purified and molecularly cloned. Similarly to human DAF, it consists of four SCRs, a Ser/Thr-rich domain and a glycosylphosphatidylinositol anchor. There is another closely related mouse DAF gene whose product has transmembrane and cytoplasmic domains instead of a glycosylphosphatidylinositol anchor. Two genes are tandemly organized within

mouse chromosome 1 near the C4-binding protein gene. Mouse Crry/p65 is a 65 kDa protein bearing both DAF- and MCP-like functions and consisting of five SCRs and transmembrane and cytoplasmic domains. The significance of functional redundancy among these mouse regulatory proteins requires clarification.

DEGRANULATION

Peter M Henson, National Jewish Center for Immunology and Respiratory Medicine, Denver, Colorado, USA

Many cells, particularly those involved in inflammatory and immunological reactions, exhibit morphologically distinct intracytoplasmic granules. Degranulation is usually taken to describe the process by which these granules or their contents are discharged to the outside of the cell. Accordingly the term is often used synonymously with secretion, discharge or release. Strictly, however, degranulation represents a state in which the granules are no longer visible microscopically, only presumptively a result of discharge, and this discharge might as well be into a phagosome as to the extracellular environment.

In vivo the phenomenon is generally assessed by histological (or ultrastructural) determination of the granularity of the cell. Quantitation here has to involve the techniques of stereology. In isolated cell populations *in vitro* it is more usually measured by secretion of the granule contents to the outside of the cell. This has the advantage of being amenable to more accurate quantitative assessment and is generally much faster. With mixed cell populations it is clearly important to use a marker that is unique to the cell or granule in question. However, the concept of degranulation came originally from the response of professional phagocytes such as neutrophils or eosinophils to the process of phagocytosis, wherein elegant cinematographic studies in the 1950s showed

the dramatic loss of phase-dense cell granules as they were discharged into the phagosome. Subsequent cell fractionation analysis placed this upon a quantitative footing.

Granules are membrane-bounded cytoplasmic storage structures in which the contents (for example, enzymes) are generally thought to exist in a state of latency, requiring changes in pH, release from a matrix, and/or hydration for optimal activity changes that accompany degranulation (into an endosome or to the outside). Cells involved in inflammation and immunological reactions tend to have at least two types of granules, those specific for the given cell type and those that represent lysosomes, although these latter may contain unique components in given cell types, for example myeloperoxidase and elastase in the 'azurophil' granule of the neutrophil. The granules that are unique to these inflammatory cells include the amine- and protease-containing granules of the mast cell and basophil, the characteristic crystal-containing granule of the eosinophil, the dense granule of the platelet and the 'specific' granules of the neutrophil. Characteristic staining properties of these granules were generally used to identify and name the particular cell – hence neutrophil, basophil and eosinophil. Similarly, the mast cell granules exhibit the characteristic meta-

chromasia with stains such as toluidine blue. Loss of this staining is used to indicate degranulation. It has been suggested that these cell-specific granules are true secretory structures, whose contents are directly released by exocytosis to the cell exterior (as well as into phagosomes in phagocytic cells). They would therefore be analogous to the secretory granules of chromaffin, pancreatic and neurosecretory cells.

By contrast, the modified lysosomal granules in this simplified concept are primarily involved in fusion with endosomes (including phagosomes). However, it is clear that in stimulation of macrophages or neutrophils, lysosomal contents are released to the exterior, although the mechanisms remain obscure. Certainly degranulation of the two major granule types of the neutrophil (whether to the outside or into the phagosome) is under separate control. The 'specific' granules are discharged earlier, leading to teleologic speculation that their largely neutral pH-effective contents have time to act before the pH of the phagosome drops and the acid-optimum contents of the azurophil granule take precedence. Calcium ionophores stimulate specific granule release, sodium or potassium ionophores secretion of the azurophil granules.

Direct exocytosis involves the movement of the granule to the plasma membrane followed by fusion of the membranes and discharge of the contents. A modification of this process is seen in mast cells in which there is an explosive degranulation involving fusion of a small section of the plasma membrane with many granules at once, either expelling the granule contents to the outside or exposing them to the extracellular milieu through a network of channels. Granule contents such as histamine are liberated from the proteoglycan matrix by ion exchange mechanisms (Figure 1). 'Piecemeal' degranulation is a process described for basophils in which the granule contents are apparently transported to the plasma membrane in vesicles. These two cell types can also regranulate, a property which may not be shared with neutrophils or eosinophils. In professional phagocytes, including macrophages, the mechanisms of secretion are less clear. Probably some granules fuse directly with the plasma membrane as they have been clearly demonstrated to do with the phagosome, some extracellular discharge occurs as a result of phagosome-granule fusion before the phagosome is closed to the extracellular environment, and some granule contents may be released as a result of vesicle transport and recycling, particularly from the modified lysosomes. In all these cell types, the degranulation appears to occur only at the sites on the plasma membrane that are stimulated. Interaction with stimuli on surfaces too large to be internalized

Figure 1 Suggested mechanisms of degranulation in inflammatory cells.

therefore results in release to the outside along the points of contact with that surface, a process termed colloquially, frustrated phagocytosis. These sites represent a protected environment under the cell which may allow secreted constituents to act on the underlying substrata even in the presence of inhibitors in the surrounding tissue fluid.

The signal transduction pathways involved in degranulation are by no means fully identified but do not seem to differ radically from those involved in other responses of these cells and include phospholipid metabolism, calcium mobilization, G proteins and kinase activation. The fungal metabolites cytochalasins B and D significantly enhance secretion in these cells by mechanisms that are not completely understood. However, the effect is employed widely to study secretion of granule contents and caution should be employed in interpreting mechanistic conclusions when these agents are present.

The accumulation of inflammatory cells in a tissue is not by itself enough to provide host defense or induce injury; it is the secretory responses of these cells that are critical, whether into a bacteria-laden phagosome or into the surrounding tissue structures. The early concept that release of contents resulted from cell lysis is now known to be significantly limited; all these cells undergo active, stimulated and highly regulated secretion of their granule contents, as well as of other materials such as newly synthesized proteins and lipids. The granule contents in particular often include highly destructive materials, including nonspecific proteases and phospholipases

as well as potent toxic cations. Their release is commonly associated with tissue destruction and disease.

DELAYED-TYPE HYPERSENSITIVITY

Alain L de Weck, Gerimmun Foundation, Allergy Research Laboratory, Fribourg, Switzerland

Definitions

‘Delayed-type hypersensitivity’ is generally understood to mean a state of reactivity characterized by inflammatory reactions starting macroscopically 6–12 h after antigen administration in a sensitized individual, reaching their peak after 24–72 h and characterized histologically by lymphocytic and mononuclear cell infiltration. This state of reactivity may not be transferred by serum but by lymphocytes of sensitized animals. Classical examples of delayed-type hypersensitivity are the tuberculin reaction, following intradermal injection of mycobacteria or of their protein extract (tuberculin) in sensitized individuals, or contact dermatitis to eczematogenous substances, such as dinitrochlorobenzene (DNCB). Historically, the tuberculin-type hypersensitivity was described by Koch, who observed that patients with tuberculosis could react with fever and generalized shock, following a subcutaneous injection of tuberculin. This general reaction was accompanied by an area of induration and swelling at the site of tuberculin injection. In the classification of hypersensitivity reactions suggested by Coombs and Gell in 1963, delayed hypersensitivity (also cell-mediated hypersensitivity or type IV) was used as a general heading to describe all hypersensitivity reactions which took more than 12 h to develop. In some more modern textbooks, it can often be read that allergic reactions of the delayed type depend upon a special subset of CD4 T lymphocytes and are essentially due to inflammatory mediators, or lymphokines, produced by these T lymphocytes.

A definition based on the macroscopic kinetics of

inflammatory reactions observed following injection of antigen in a sensitized animal may be misleading. While the macroscopic and morphologic description of classical delayed-type hypersensitivity reaction appears most of the time to follow the kinetics indicated above (onset after 6–12 h, peak after 24–72 h), there are numerous exceptions and the same immunological mechanisms may lead to different time courses. First, the kinetics may vary when the contact between antigen and sensitized lymphocytes occurs in areas other than the skin. Furthermore, some reactions where similar cellular elements are involved may evolve over a period of weeks, or even months (granulomatous reactions). Some authors therefore prefer the general term of ‘delayed-onset hypersensitivity’.

Two modes of delayed-type hypersensitivity are frequently observed:

1. A *permanent* type, persisting for several months or years after completion of the sensitization process, and which corresponds to classical tuberculin-type hypersensitivity. In this case, the inflammatory reaction is still very marked 72–96 h after intradermal injection of antigen.
2. A *transient* type, morphologically very similar, but which disappears 1–2 weeks after induction of sensitization. In this case, the inflammatory lesion peaks at 24 h and has practically disappeared after 48–72 h. This form is also called ‘Jones–Mote hypersensitivity’.

In guinea pigs, reactions with very similar kinetics and also implying cellular infiltrations, but in which basophils may predominate (‘cutaneous basophil

hypersensitivity'), have been described, but they may be sometimes due to antibodies.

The processes leading to delayed-type hypersensitivity reactions may be divided into three phases:

1. A *sensitization phase*, including formation and presentation of antigen to immunocompetent cells.
2. A *development phase*, including the production of specifically sensitized lymphocytes.
3. Upon renewed antigen administration, an *effector phase* in which the interaction of sensitized lymphocytes with antigen leads to the characteristic inflammatory reaction.

Sensitization phase

A large variety of antigens may induce delayed-type hypersensitivity (DTH). Usually, particulate antigens, such as bacteria, viruses or parasites, seem particularly to favor this type of hypersensitivity. Intradermal injection of foreign proteins or application on the skin of reactive chemical substances of low molecular weight, capable of forming conjugates with autologous carrier proteins, also frequently induce DTH. Polysaccharides, on the other hand, are less prone to cause DTH. The mode of administration of antigen also seems to play a role. Intravenous injection is usually not efficacious in inducing DTH. The incorporation of antigen in some adjuvants, in particular in complete Freund's adjuvants containing mycobacteria, is very favorable for establishing DTH. The role of macrophages in antigenic presentation is also important. Failure to provide proper antigenic presentation by macrophages usually leads to lesser induction of DTH, even if antibodies may be formed. The fate of antigen in the organism, for example after application on or injection into the skin, probably also plays an important role in induction of sensitivity. It has been shown that the integrity of afferent lymphatic channels and of regional lymph nodes is needed for establishment of DTH. It is therefore very likely that the first recognition of antigen and presentation to T lymphocytes occurs in the regional lymph nodes. However, to this concept of 'central sensitization' can also be added examples of 'peripheral sensitization'. In the induction of contact eczema or in skin transplantation, it has been shown that local persistence of antigen for a while is required for the induction of the process, even when large amounts of soluble antigens quickly reach the regional lymph nodes. In that case, antigen presentation and recognition may occur at the level of local antigen deposits by T lymphocytes and macrophages freely moving through tissues and returning through afferent lymphatic channels to the

regional lymph nodes. The role of dendritic cells in the epidermis (Langerhans cells), which possess several macrophage-like properties, has been particularly emphasized.

Development phase

Kinetic examination of cellular changes in regional lymph nodes following local administration of antigen has shown that some of the thymus-dependent lymphocytes, which accumulate in the paracortical zone of the lymph nodes, start to proliferate from the 2nd day on and reach, 3–4 days after first contact with antigen, an immunoblastic, proliferative stage. These immunoblasts (large pyroninophilic cells) revert after mitotic division to small lymphocytes, which appear to be specifically sensitized and are the expression of amplification of some predetermined clones. However, the large proportion of immunoblasts in the lymph node cell population suggests that this proliferation is also to some extent polyclonal, probably under the effect of mitogenic lymphokines. The acquisition of specific T lymphocytes, able to produce a DTH reaction, may be evaluated by passive transfer of lymph node cells taken at various times after initial antigen administration. Such passive transfer experiments have shown that specifically sensitized T cells are present in local regional lymph nodes and cause local inflammatory reactions upon renewed contact with antigen. These transfer experiments have also enabled the identification of some T lymphocyte subsets as specifically reactive elements with antigens and responsible for DTH reactions in guinea pigs and in mice. Current evidence suggests that a special subset of CD4⁺ T_H1 lymphocytes is responsible as primary effector cells in DTH reactions.

Recent findings suggest that the nature of antigen presentation by dendritic cells and the lymphokine microenvironment play a decisive role in CD4⁺ T cell development leading to suitable effector T lymphocyte subsets for DTH. Interleukin 12 (IL-12) favors T_H1 development and DTH, while IL-10 antagonizes the development of T_H1 cells and favors T_H2 lymphocytes. However, there is also evidence that several subsets of lymphocytes may be implicated in DTH and that the T_H1/T_H2 dichotomy may be an oversimplification.

Effector phase

Renewed application or injection of antigen into the skin of a sensitized individual induces an inflammatory reaction, which may start within 6–12 h with some erythema, accompanied by progressive tissue

induration reaching its peak after 24–72 h. When the antigen is simply deposited on the skin, such as in contact dermatitis, dermal cellular infiltration is accompanied by epidermic lesions, such as spongiosis and formation of vesicles. Although the morphological aspects of contact dermatitis and tuberculin-type hypersensitivity reactions do differ somewhat, which has led some authors to consider these two types of reaction as entirely separate, the differences appear rather to be due to different local concentrations of antigen at the dermal or epidermal level, but they do not reflect fundamental differences in mechanisms.

Contact hypersensitivity is mainly an epidermal phenomenon in which the main antigen-presenting cell is the Langerhans cell. Langerhans cells are dendritic and express the cortical thymocyte antigen CD1 and major histocompatibility complex (MHC) class II antigens. They can also be found in the afferent lymph and paracortical area of lymph nodes as early as 4 h after epicutaneous application of a contact allergen in mice. The earliest histological change in the challenge reaction of contact hypersensitivity is observed after 3–4 h, when a mononuclear cell infiltrate is noticed around blood vessels. The infiltrate with mononuclear cells consists essentially of CD4⁺ lymphocytes, with a lesser number of CD8⁺ cells. Some increase in the expression of activation antigens (e.g. HLA-DR) by keratinocytes indicates that epidermal cells may also be implicated.

In tuberculin-type reactions, in which antigen is primarily deposited in the dermis, dermal perivascular infiltrates predominate and usually peak around 48 h. In this infiltrate CD4⁺ cells outnumber CD8⁺ cells by about 3:1, CD1⁺ cells (Langerhans-like) are also found. Polymorphs are rather uncommon in humans, but macrophages and monocytes also accumulate around dermal vessels by 12 h. Many of the infiltrating lymphocytes and macrophages express activation antigens, such as HLA-DR.

Functional analysis of such reactions has clearly shown that they occur in two stages. In a first specific stage, antigen comes into contact with sensitized T lymphocytes which are present as a very small proportion of the total T lymphocyte population normally migrating from blood vessels throughout tissues, to return then through lymphatic channels to regional lymph nodes and to the blood circulation. This specific interaction with antigen stimulates lymphocytes to synthesize and release in the tissues various proinflammatory cytokines. One of the first manifestations of inflammation consists of an augmentation of capillar permeability and increased blood flow, which favor cellular influx into tissues as well as liquid extravasation and deposition of certain

blood proteins. Fibrin deposits, not cellular infiltration as usually believed, are responsible for the induration phenomenon characteristic of DTH, as induration may be totally suppressed by anticoagulants. How far the concomitant activity of perivascular mast cells carrying immunoglobulin E (IgE) of the same antigen specificity, as well as vasoactive amines, such as serotonin, or factors produced by T cells enhancing capillary permeability are also involved remain topics for investigation.

During a second nonspecific phase, various cellular types are attracted into the reaction site, essentially monocytes and small lymphocytes, more rarely basophils or eosinophils. Transfer experiments have clearly shown that the great majority of cells participating in the tissue infiltration are nonspecific.

Pathophysiological analysis of DTH reactions has implicated different chemotactic mediators in the accumulation of the cellular infiltrate. There are probably also some factors inhibiting cellular migration, in order to explain accumulation of cells in the tissues, which otherwise would be normally evacuated through lymphatic vessels. Many of the cells involved are in a state of activation, as manifested by the appearance of surface activation antigens (e.g. HLA-DR). The production of various lymphokines such as IL-2 and interferon α has been detected by *in situ* hybridization and is involved in cellular proliferation in DTH reaction sites. There are also manifestations of cellular toxicity at the local level, for example in transplant rejection, which may be due to the local production of lymphotoxins. The role of cytokines in DTH reactions was first supported by indirect arguments, such as: 1) the production of very similar inflammatory lesions upon intradermal injection of lymphokine-containing T cell culture supernatants or of purified lymphokines; 2) similar effects on inhibition of migration of peritoneal macrophages *in vivo* ('macrophage disappearance reaction'); 3) cellular chemotactic effects *in vivo* by extracts from local DTH reactions; 4) the presence of various lymphokines in the serum of animals or humans undergoing a general DTH reaction; 5) the suppression of DTH reactions by some antilymphokine antibodies. Experiments using *in vitro* hybridization techniques now permit us to follow directly the synthesis of various cytokines in DTH reactions. In particular, IL-2 and interferon α seem to play an important role.

The development of DTH lesions in tissues appears increasingly as a complex event in which, beyond antigen-specific T lymphocytes subsets and monocytes, a number of local cells may be implicated. These are: 1) keratinocytes producing proinflammatory cytokines (e.g. interferon γ); 2) mast

cells and platelets; 3) endothelial cells releasing L- and P-selectins and mediating selective local attachment of T lymphocytes. Among mediators released by such cells, histamine, serotonin and leukotrienes all appear to contribute to DTH inflammation.

Delayed-type hypersensitivity reactions may become chronic and protracted, taking the form of granulomatous hypersensitivity, which may be clinically the most important form of DTH. It often results from the presence within macrophages of some persistent agent, usually a microorganism, which the cell is not able to destroy. On other occasions it may be caused by the continuous presence of antigen in particulate or immune complex form. The histological appearance of the granulomatous reaction is quite different from the tuberculin-type reaction and is characterized by the abundance of epithelioid cells, which are believed to derive from activated macrophages. The immunologically induced granulomatous lesions usually possess a core of epithelioid cells and macrophages, sometimes with giant cells; the central area may become necrotic. The macrophage epithelioid core is surrounded by a cuff of lymphocytes; there is often also considerable fibrosis and deposition of collagen fibers.

Clinical manifestations

Delayed-type hypersensitivity reactions are a prominent feature of several chronic diseases in humans, which for the most part are due to infectious agents, such as mycobacteria, protozoa and fungi. Important diseases include tuberculosis, leprosy, listeriosis, leishmaniasis, deep fungal infections (e.g. blastomycosis) and helminthic infections (e.g. schistosomiasis). These diseases are caused by pathogens which represent a persistent, chronic, antigenic stimulus. In such cases, protective immunity and delayed hypersensitivity often occur but are not always coincidental.

Instead of discussing these various DTH-related diseases, it may be more useful to describe under more general terms the various types of DTH reactions which may be encountered.

Local reactions

Most descriptions of DTH are based on local reactions following application or injection of antigen into the skin. These reactions are easiest to follow experimentally and are also frequently used from a diagnostic point of view (cutaneous tests). However, these local reactions, described in detail above, are not the only possible manifestation of clinical DTH.

Focal reactions

In most local reactions, antigen is eliminated after a few hours or a few days, in particular by activated macrophages. When antigen cannot be eliminated, a local chronic inflammation may occur in the form of a granuloma. In that case, any new massive parenteral administration of antigen may provoke a violent focal reaction following interaction of antigen with locally accumulated sensitized lymphocytes: this manifests as marked flare-up of the chronic inflammatory process. A historical example of focal reaction is the sudden aggravation of tuberculous lesions following intravenous injection of tuberculin, first attempted by Koch in the treatment of tuberculosis. Such reactions may still occasionally be observed after intradermal injection of too high a concentration of tuberculin. Similar focal reactions, for example in dental granulomas, sinusitis, etc., are frequently observed clinically. Flare-up reactions after new parenteral administration of antigen at the site of previous local DTH reactions may also be due to similar pathophysiology, but they are sometimes also due to local accumulation of plasma cells and specific antibodies.

Generalized DTH reaction

Generalized DTH reactions following parenteral administration of antigens are also frequent. The most classical example, which is rarely observed nowadays, is the tuberculin shock accompanied by fever. Some of the cutaneous reactions accompanying viral infections (morbilliform exanthema in measles) are probably of the same nature, as well as generalized hypersensitivity reactions to drugs. In that case, lymphokines may be detected in the serum during the acute phase. Such reactions often occur within 4–6 h of antigen administration and are therefore not 'delayed'.

In summary, although the kinetics and characteristics of DTH reactions may vary according to the mode of administration of antigen and to the tissue in which the reaction takes place, a common triggering mechanism in which T lymphocytes and lymphokines play a major role gives a clear-cut identity to this chapter of immunopathology.

DENDRITIC CELLS

Jonathan M Austyn, Nuffield Department of Surgery, University of Oxford, John Radcliffe Hospital, Oxford, UK

Dendritic cells (DCs) are a lineage of specialized antigen-presenting cells (APCs) that play a central role in the initiation of adaptive immune responses. Since the first description by Steinman and Cohn in 1973 of the lymphoid DC as a trace cell type isolated from lymphoid tissues of mice, it has become clear that cells of this leukocyte lineage are widely distributed throughout lymphoid and most nonlymphoid tissues of all mammalian species studied. DCs have or can acquire a phenotype distinct from that of other leukocyte lineages (Table 1).

It is convenient to distinguish between different stages of DC according to the cells' specialized functions in different anatomical compartments. 1) DC progenitors originate from the bone marrow (BM) of adult mammals and enter the blood to seed the tissues. 2) Within nonlymphoid tissues the cells develop into the so-called 'immature' or, perhaps better, 'processing' stage, with optimal capabilities for the uptake and processing of foreign antigens, MHC (major histocompatibility complex) production, and the formation of foreign peptide-MHC complexes. 3) The cells begin to mature, and migrate from nonlymphoid tissues into secondary lymphoid tissues. 4) In secondary lymphoid tissues, DCs at the 'mature' or 'costimulatory' stage present foreign peptide-MHC complexes to resting T cells and have acquired the capacity to deliver specialized costimulatory signals for T cell activation, a crucial step in the induction of most adaptive immune responses. 5) DCs within the thymus may present self peptide-MHC complexes to developing thymocytes for tolerance induction.

In contrast to cells of the DC leukocyte lineage, the follicular dendritic cell (FDC) probably represents a distinct cell type that is not BM derived, can express membrane-bound native antigens in immune complexes for prolonged periods, and plays a role in B cell (humoral) responses.

Dendritic cell progenitors

Progenitors *in vivo*

The bone marrow (BM) origin of DCs is well established from studies with radiation-induced BM chimeras, in which replacement of host DCs by donor-derived cells can be visualized. It seems probable that DC progenitors seed most tissues, but the present lack of markers for the cells at this early stage precludes precise estimates of their numbers. Stimuli that recruit DC progenitors into tissues include granulocyte-macrophage colony-stimulating factor (GM-CSF), since, for example, local production of GM-CSF increases the numbers of DCs in human lung and some lung cancers, and increased numbers of DCs are present in the dermis of human skin after intradermal administration of this cytokine. Bacterial lipopolysaccharide (LPS), or cytokines elicited by this agent, recruits DC progenitors to rat lung, and mouse heart and kidney, following aerosol and systemic administration of LPS, respectively.

Following transplantation of rat liver to allogeneic recipients, donor-derived DC progenitors can be detected in host BM, suggesting that DC progenitors from at least some nonlymphoid tissues may seed other sites. After transplantation of human livers,

Table 1 Phenotype of dendritic cells^a

Molecule	Expression on DCs ^c and comments	Status ^b
CD1	CD1a expressed by human DCs cultured from progenitors and by epidermal LCs. CD1c expressed by human lymph node DCs. Structurally related to MHC class I molecules and can act as ligands for some $\alpha\beta$ and $\gamma\delta$ T cells	
CD4	Expressed by a subset of <i>human</i> blood DCs that may be derived directly from the bone marrow (CD4 downregulated on culture), and by human epidermal LCs and DCs in other epithelia. Expressed by <i>rat</i> veiled cells. Binds MHC class II molecules and a receptor for HIV in human	
CD8	Expressed by a subset of <i>mouse</i> DCs in spleen as $\alpha\alpha$ homodimers, and by DCs in thymus, some of which express $\alpha\beta$ heterodimers. Binds MHC class I molecules	
CD10	Expressed by human bone marrow progenitors that apparently give rise to DC, T cells, B cells and NK cells	P
CD11a/CD18: LFA-1	Weakly or not expressed by epidermal LCs, but expressed by many other DCs. Ligands are CD54 (ICAM-1), ICAM-2 (CD102) and ICAM-3 (CD50)	
CD11b/CD18: CR3	Expressed by most DCs but often at low levels. The type 3 complement receptor; ligands include iC3b, fibrinogen and cell wall components of some bacteria and protozoa	
CD11c/CD18: p150,95	In <i>mouse</i> expression is relatively restricted to most or all DCs in lymphoid tissues	+
CD14	Not expressed by most DCs. Transient expression by DCs cultured from progenitors is possible. The receptor for LPS complexed with LPS-binding protein expressed by monocytes/macrophages and FDCs	(0)/F
CD18	See CD11a, CD11b and CD11c. The common β_2 integrin subunit	
CD19	Not expressed by DCs. Expressed by all human B cells, some B cell precursors, and FDCs	0/F
CD21: CR2	Not expressed by DCs. The type 2 complement receptor expressed on mature B cells and FDCs. Receptor for EBV	0/F
CD23: Fc ϵ RII	Human epidermal LCs express the Fc ϵ RIIb form of CD23, the low-affinity receptor for IgE. Note: High affinity IgE receptors (Fc ϵ RI) are also expressed by epidermal LCs	
CD25	Expressed by maturing DCs such as mouse LCs and rat veiled cells, but its function on these cells is unknown. The IL-2 receptor α (p55) chain	
CD32: Fc γ RII	Expressed by human and mouse epidermal LCs but downregulated during maturation. May target antigens to intracellular processing compartments and enhance antigen presentation. The Fc receptor for aggregated and antigen-complexed IgG	
CD34	Expressed by immature hematopoietic cells, including DC progenitors in human and mouse bone marrow and blood	P
CD35: CR1	Not expressed by DC. The type 1 complement receptor expressed for example by B cells and FDCs	0/F
CD40	Expressed by DCs cultured from progenitors and by DCs in lymphoid tissues. A costimulatory molecule for T cell activation. CD40 ligand (gp39) stimulates maturation of presumptive DCs cultured from human blood monocytes	
CD44: Pgp-1	Expressed by mouse epidermal LCs and interstitial DCs (e.g. heart). CD44 is differentially spliced. Different isoforms may be expressed by DCs: for example, CD44-v5 and -v6 may be upregulated during mouse LC maturation, and CD44-v9 is induced during maturation of human DCs grown from progenitors. Ligand is hyaluronate	
CD45: LCA	Expressed by essentially all DCs. CD45 is differentially spliced; isoforms expressed by DCs not yet studied in detail	
CD49	Expressed by epidermal LCs and lymphoid DCs. CD49 is a family of integrin chains of the very late antigens (VLA) associated generally with CD29. Mouse LCs express little VLA-4 (CD49d) but some cells have high levels of VLA-6 (CD49f); the converse is true for DCs isolated from lymph nodes. Ligands include CD106 (VCAM-1) for CD49d/CD29 and laminin for CD49f/CD29	
CD54: ICAM-1	Not detectable on epidermal LCs, expressed on DCs grown from progenitors, and upregulated to high levels during maturation of DCs (e.g. on DCs in lymphoid tissues). A ligand for CD11a/18 (this interaction enhances T cell activation) as well as CD11b/CD18 (CR3). The major rhinovirus receptor in human	
CD58: LFA-3	Expressed by some DCs. Ligand is CD2, e.g. on T cells	

Table 1 Continued

<i>Molecule</i>	<i>Expression on DCs^c and comments</i>	<i>Status^b</i>
CD74: li	Freshly-isolated epidermal LCs exhibit a high rate of CD74 biosynthesis but this is shut off during maturation in culture; may also apply <i>in vivo</i> and to other nonlymphoid DCs. The MHC class II-associated invariant chain	I
CD80: B7-1	Expressed at low levels by mouse and human epidermal LCs but upregulated during maturation, and expressed by lymphoid DCs. A costimulatory molecule. Ligands are CD28 and CTLA-4 on T cells	
CD83	Expressed by <i>human</i> DC cultured from progenitors, human blood DC, LCs and DCs in lymphoid tissues on mature cells	*
CD86: B7-2	No or low-level expression on epidermal LCs but dramatically upregulated during maturation and expressed by interdigitating cells in lymphoid tissues. Reportedly expressed by mouse DCs in other epithelial sites (e.g. lung but not gut) and in some interstitial spaces (e.g. heart but not kidney). A major costimulatory molecule. Ligands are CD28 and CTLA-4 on T cells	
CD88: C5aR	Expression upregulated during maturation of epidermal LCs, and expressed by interdigitating cells in lymphoid tissues. The C5a receptor	
CD95	Expressed by some DCs. Fas receptor	
CDw116	Expressed by DC progenitors (inferred) and by epidermal LCs. The GM-CSF receptor	
CD117: <i>c-kit</i>	Expressed by DC progenitors (inferred). The stem cell factor (SCF) receptor	
CD120	Expressed by DC progenitors and epidermal LCs (inferred). The TNF receptor(s)	
CD2w121	Expressed by epidermal LCs (inferred). The IL-1 receptor(s)	
Chemokine receptors	CCR5 specific for RANTES, MIP-1 α and MIP-1 β , and CXCR4 (or fusin) specific for SDF-1 are expressed by DC; HIV co-receptors in human	
CLA	Expressed by DC progenitors that can give rise to DCs containing Birbeck granules in culture. The cutaneous lymphocyte-associated antigen	P
DEC 205	Expressed by <i>mouse</i> epidermal LCs and by subsets of DCs in lymphoid tissues, and may target antigens to processing compartments. DEC 205 is structurally related to the mannose receptor (see below); ligands under investigation. Identified by the NLDC-145 monoclonal antibody	
HSA, J11d	Expressed by epidermal LCs and perhaps subsets of DCs in lymphoid tissues in <i>mouse</i> . A costimulatory molecule for CD4 ⁺ T cells. The heat-stable antigen	
Mannose receptor	Expressed by presumptive DCs cultured from human blood monocytes, and targets mannosylated antigens to processing compartments. The macrophage mannose receptor. See also DEC 205	
MHC class I	Classical MHC class I molecules are probably expressed by all DCs after the progenitor stage. Expression of nonclassical molecules has not been well studied. See also CD1	
MHC class II	MHC class II molecules may be expressed by some DC progenitors and by all DCs after the progenitor stage, and expression can be upregulated (e.g. during maturation of LCs). In human, lymphoid DCs reportedly express HLA-DP, -DQ and -DR products. See also CD74	
MRC OX62	Expressed by some lymphoid and nonlymphoid DCs in <i>rat</i> . Also expressed by some $\gamma\delta$ T cells. May be an integrin	*
2A1	An intracellular antigen of <i>mouse</i> DCs that is expressed during maturation. Appears localized to a late endosomal compartment. See also M342	*, I, >
33D1	A marker of a subset of DCs in <i>mouse</i> lymphoid tissues	*
F4/80	Expressed by <i>mouse</i> epidermal LCs and downregulated during maturation. A molecule with homology to G protein-linked 7 transmembrane hormone receptor family members	
M342	Expression and distribution similar to 2A1	*, I, >
NLDC-145	See DEC 205	*
S100	An intracellular molecule expressed by <i>human</i> LCs, and often taken as indicative of DCs in other sites	I

^aExamples of molecules expressed by DCs at different stages of development and in different anatomical compartments, focusing on human and mouse DCs but including comments on rat DCs where relevant.

^bStatus of molecule: *, molecule that can be used as a marker of DCs rather than of most other cell types; 0, not expressed by DCs; P, expressed only at progenitor stage; >, expression increased during DC maturation; <, expression decreased during DC maturation; F, molecule expressed by FDCs but not DCs; I, intracellular expression.

^cSpecies specificity is indicated by *italics*. In some cases (e.g. CD4 versus CD8 expression on human and rat versus mouse DCs, respectively; mouse CD11c expression) this is likely to be absolute. In other cases, homologous molecules showing a similar distribution may be identified in other species.

donor-derived cells resembling DCs can also be detected in other recipient tissues such as skin, and it has been suggested that such a state of 'microchimerism' is necessary for transplantation tolerance, although this is not yet proven.

Culture of progenitors

DCs can be generated *in vitro* from BM and blood progenitors cultured in cytokines, but the precise branch point for differentiation of DCs from other leukocyte lineages is not completely determined. 1) DCs can be grown from mouse CD34⁺ MHC class II-negative BM and blood progenitors cultured in the presence of GM-CSF, or from human BM and cord blood progenitors cultured in GM-CSF plus tumor necrosis factor α (TNF α). Production of mixed colonies of mouse DCs, macrophages and neutrophils implies the existence of a common committed stem cell (e.g. the mouse granulocyte-macrophage colony-forming unit or CFU-GM). In human BM, a clonogenic progenitor (termed CFU-DC) has been identified that generates pure colonies of DCs and which can be expanded in the presence of *c-kit* ligand (stem cell factor). Cytokines such as *flt-3* ligand may also induce proliferation of DC progenitors and increase production of DC *in vitro* and *in vivo*. 2) DCs can be generated that either do or do not possess Birbeck granules, an endocytic organelle present in Langerhans cells of several species but not in interstitial DCs (see below), depending on whether CD34⁺ progenitors express CLA (Table 1) or not, respectively. This indicates that the recruitment of DCs to different anatomical sites may be determined, in part, at the progenitor level. 3) Subsets of human CD34⁺ MHC class II-positive BM cells and mouse thymic lymphoid precursor cells may give rise to both DCs and lymphoid (mouse T, or human T, B and natural killer (NK)) cells but not myeloid cells. This suggests either that a distinct DC progenitor(s) seeds the thymus, or that this differentiation pathway is induced by the particular cytokine or hormonal milieu of this tissue. 4) Cells closely resembling DCs can be cultured from human peripheral blood low-density adherent cells (monocytes), with GM-CSF plus interleukin 4 (IL-4) generating an 'immature' or 'processing' stage, and subsequent exposure to TNF α , IL-1, CD40 ligand or LPS promoting further maturation.

Further development of these approaches for production of DCs *in vitro* is likely to lead to new immunotherapeutic strategies using DCs *in vivo*. Such cells grown from BM and pulsed with relevant antigens have been used to induce antitumor immunity in mice, for example, and related clinical trials are now underway.

Nonlymphoid dendritic cells

DCs in nonlymphoid tissues perform a sentinel function in acquiring foreign antigens before maturing and migrating to secondary lymphoid tissues for initiation of many immune responses. Hence, in general, the cells *in situ* represent the immature or processing stage of the lineage.

1) DCs are present within skin and the epithelia of the respiratory, gastrointestinal and urogenital tracts. The DCs of skin, Langerhans cells (LCs), form a ramifying network throughout the epidermis, together, in mouse but not human, with epidermal $\gamma\delta$ T cells whose functions have yet to be ascertained. It is estimated that the half-life of LCs in unperturbed skin epidermis is likely to range from weeks to even a month or two. Precursors to LCs are probably present within the dermis of skin, in which a population of so-called dermal dendrocytes has been identified. Similar cells are distributed throughout the lung and airways, but are juxtaposed to macrophages which appear to regulate DC function by maintaining the transiently resident DCs at an immature stage. In gut, the lamina propria contains large numbers of DCs. In rats, following oral feeding or intraintestinal injection of antigen, and after aerosol administration of antigens to the lung and airways, DCs from these sites can present the antigen to sensitized T cells *in vitro* and can prime naive recipients after adoptive transfer *in vivo*. 2) DCs are present in the interstitial spaces of all solid organs, with the exceptions of the bulk of the central nervous system and some other sites considered to be 'immunologically privileged' such as the testis. Interstitial DCs probably acquire antigens that gain access to these sites. The half-life of interstitial DCs, such as those in heart, may range from a few days to a week or so. 3) The liver may represent a special case, in that DC progenitors may be recruited to the liver sinusoids, develop into the processing stage, and acquire particulate and perhaps other antigens that enter the bloodstream.

Maturation and migration of dendritic cells

Maturation

DC maturation commences in nonlymphoid tissues and may continue within secondary lymphoid tissues. Maturation involves profound phenotypic and functional changes as the cells convert from the processing to the costimulatory stages. These events have been well studied in the case, for example, of LCs. 1) Freshly-isolated epidermal LCs express membrane receptors, some of which can target antigens

into cellular processing compartments (e.g. CD32 and mouse DEC205; Table 1); internalize soluble and certain particulate antigens (pinocytosis and phagocytosis); contain acidic compartments associated with processing of exogenous antigens (endolysosomes and specialized CIIV and MIIC), synthesize MHC class II and invariant chain molecules; assemble peptide-MHC complexes which are transported to the cell surface; and produce some cytokines (e.g. IL-1 β) and chemokines (e.g. MIP-1 α , MIP-1 γ , MIP-2). The cells have little or no costimulatory activity. 2) In the presence of GM-CSF, and in synergy with IL-1 but not TNF α in mouse, cultured LCs downregulate some receptors (e.g. CD32 but not DEC205); lose phagocytic activity and many acidic compartments; shut off MHC class II and invariant chain synthesis; and exhibit a different cytokine profile (e.g. increased IL-1 β and IL-12 but decreased MIP-1 α and MIP-2 production). However, surface expression of peptide-MHC complexes increases and the cells acquire costimulatory activity associated with new or increased expression of molecules such as CD40, CD80 and CD86 (Table 1). Broadly speaking, these events are likely to occur during maturation of LCs *in vivo* and are likely to apply to other nonlymphoid DCs. Mice that lack the *relB* subunit of the NF κ B transcription factor have LCs in skin, but appear to lack lymphoid DCs and have highly disorganized lymphoid tissues. Hence, *relB* expression may be essential for development or maturation of at least some DCs.

Migration

Migration from nonlymphoid tissues (and presumably maturation) is promoted by locally-produced inflammatory cytokines and other agents that may be generated during local infection or trauma. For example, IL-1 β and TNF α (the latter perhaps produced in a paracrine loop induced by IL-1 β *in vivo*) may promote migration of LCs from mouse skin, and LPS or LPS-induced cytokines such as TNF α (or LPS itself) may promote migration of DCs from rat gastrointestinal tract and from mouse heart and kidney and probably other nonlymphoid sites.

As a general rule, DCs from epithelia may migrate exclusively via afferent lymph into regional lymph nodes, whereas DCs from interstitial spaces migrate both via afferent lymph to nodes and via the blood to spleen. 1) The DCs of afferent lymph, so-called 'veiled cells' because of their distinct cytological features (namely the presence of sheet-like lamellipodia), appear heterogeneous in phenotype and function and can be viewed as representing a transitional stage from processing to costimulatory DCs. The flux of DCs in afferent lymph draining normal

skin is considerably enhanced following topical application of agents such as contact sensitizers, probably because of the local inflammatory response induced in the skin. In mouse skin transplants and explants, LCs can be visualized moving from epidermis and into dermal lymphatics before leaving the tissue; this process is accompanied by maturational changes. There is also a considerable traffic of DCs from lamina propria of gut, and these cells can be collected from rat central lymph after mesenteric lymphadenectomy. In general, agents such as LPS or LPS-elicited cytokines appear to recruit DC progenitors into local sites from which the immature cells are leaving, presumably to replace the local DC pool; these events have also been documented for DCs in rat lung following administration of certain bacteria. 2) Peripheral blood contains at least two populations of DC: recently-produced DC progenitors traveling from BM to tissues (these cells may express CD4 in human), and DCs from nonlymphoid tissues traveling to spleen. The latter route is evident from the finding that DCs migrate from mouse cardiac allografts and can be detected in recipient spleens. 3) There may be a specialized route for DC migration from liver sinusoids into celiac nodes for initiation of responses to bloodborne antigens: following celiac lymphadenectomy of rats and intravenous delivery of a phagocytic load, particle-laden DCs can be isolated from central lymph, but these cells are not present after mesenteric lymphadenectomy.

Lymphoid dendritic cells

DCs in secondary lymphoid tissues

DCs isolated from secondary lymphoid tissues such as spleen, lymph node and Peyer's patch are potent stimulators of immune responses *in vitro*. These include: T cell proliferative responses to specific antigens (e.g. in transgenic T cell systems), alloantigens (i.e. allogeneic mixed leukocyte reactions), superantigens, and mitogenic stimuli (e.g. oxidative mitogenesis); T-dependent antibody formation; and cytotoxic T lymphocyte generation through both CD4-dependent and CD4-independent pathways. DCs are probably required for responses of memory, as well as resting T cells, whereas activated T cells can respond to other types of APC as well as DCs. The potency of lymphoid DCs can at least in part be attributed to their capacity to form antigen-independent clusters with resting T cells, expression of relevant peptide-MHC complexes and expression of costimulatory molecules such as CD40, CD80 and CD86. In addition, lymphoid DCs can produce high levels of IL-12, which promotes development of T_H1 responses of CD4⁺ T cells. Bulk populations of

lymphoid DC suspensions are capable of antigen uptake and processing to some extent, indicating that at least some DCs in secondary lymphoid tissues may not be fully mature. For example, some lymphoid DCs are phagocytic *in vitro* (although this activity is lost during culture) and antigen-pulsed lymphoid DCs can sensitize naive recipients after adoptive transfer *in vivo*.

An important and distinctive feature of DCs is their capacity to home to discrete regions of lymphoid tissues *in vivo*. For example, DCs home from afferent lymph into the subcapsular sinus of lymph nodes and thence to the interfollicular and paracortical (T) areas; and from the blood into the marginal zone of spleen and thence to white pulp, probably traversing peripheral white pulp (B areas) before localizing in central white pulp (T areas). Hence at least some DCs in secondary lymphoid tissues originate from peripheral sites, although some cells conceivably develop from progenitors entering directly from the BM.

Lymphoid tissues such as mouse spleen and Peyer's patch contain two phenotypically distinct subsets of DC, and the same is likely to be true of lymph node and to pertain to other species. Within mouse spleen, interdigitating cells (IDCs) are localized in central white pulp (PALS) juxtaposed to the bulk of resting T cells, while in the marginal zone 'nests' of DCs have been described that may ultimately give rise to IDCs. The phenotype of these cells, based on the use of DC-restricted monoclonal antibodies is, respectively, N418⁺ NLDC145⁺ 33D1⁻ 2A1⁻ M342⁺ and N418⁺ NLDC145⁻ 33D1⁺ 2A1⁻ M342⁻ (Table 1). Similar subsets have been described in mouse Peyer's patch, with DCs in deep interfollicular (T cell) regions being clearly distinguishable from DCs in the more superficial subepithelial dome region (and which may acquire antigens transported from the gut across M cells of the patch). A small subset of DCs, distinct from FDCs, has also been identified within germinal centres. It is possible, though not yet proven, that DCs can enter these sites during secondary responses or later in primary responses, for example after antibody has been formed.

DCs do not appear to leave secondary lymphoid tissues, either via efferent lymph from lymph nodes or via blood from the spleen. Instead, it seems likely that the cells may be removed by apoptosis, either as part of a regulated differentiation process or after interaction with activated T cells (e.g. through Fas-Fas ligand interactions). The half-life of DCs in spleen, for example, is short and probably ranges from 2 to 3 days only.

DCs in thymus

DCs isolated from thymus are similar to DCs isolated from secondary lymphoid tissues in their capacity to activate resting T cells. However, within the thymus, DCs may interact with developing thymocytes and induce central tolerance (negative selection). A large body of evidence, from studies with radiation-induced BM chimeras for example, attests to the capacity of BM-derived cells to induce negative rather than positive selection of T cells. Experiments in which organ cultures of mouse embryonic thymus lobes were reconstituted with DCs have shown that these cells can indeed delete potentially autoreactive thymocytes. Similar findings after injection of DCs into mouse thymus *in vivo* have also implicated DCs in tolerance induction, although both clonal deletion and clonal inactivation (anergy) have been reported. Within the thymus, MHC class II-positive DCs are situated at the corticomedullary junction and within the medulla (thymic IDCs), and DCs added to organ cultures of mouse embryonic thymus lobes home to this region. It is possible a distinct DC progenitor within thymus can give rise to both DCs and T cells (see above). Whether or not DCs can also induce peripheral tolerance is currently under investigation.

DEOXYGUANOSINE

Erwin W Gelfand, Department of Pediatrics, National Jewish Medical and Research Center, Denver, Colorado, USA

The discovery in 1972 that an inherited disorder of adenine nucleotide metabolism was associated with a specific immunodeficiency disease in humans stimulated a major resurgence of interest in the metabolism and effects of purine nucleosides. The association of disorders of purine nucleoside catabolism with severe immunologic dysfunction provides compelling evidence for the role of these metabolic pathways in the biochemical control of lymphocyte differentiation and function. The link between the biochemical explanations for the immunologic disorders, the remarkable tissue specificity of the diseases, and the pathologic effects of these inborn errors of metabolism remains somewhat uncertain.

Purine nucleoside phosphorylase deficiency

Deficiency of the enzyme purine nucleoside phosphorylase (PNP) usually results in the appearance of signs and symptoms of immunodeficiency between the ages of 3 and 18 months. There is a striking dichotomy between T and B cell immunity in these patients. Humoral immunity, B cells, B memory cells, and plasma cell differentiation are generally intact. Indeed, the presence of autoantibodies and elevated immunoglobulin levels are usually present. In contrast, T cell immunity is markedly affected. Although T cell precursors appear to be present, peripheral T cell lymphopenia in the circulation and lymphoid

tissues is profound, accounting for the rather selective deficiency of cell-mediated immunity. Although the T cells that are present may be immature and proliferate poorly, they are capable of providing helper cell activity for B cell maturation. The most significant metabolic abnormality found in PNP-deficient patients is the elevated deoxyGTP levels in erythrocytes and urine.

Deoxyguanosine metabolism

The structural gene for PNP in humans has been assigned to the q13 band of chromosome 14. The enzyme is ubiquitous in human tissues with the highest specific catalytic activities in peripheral blood lymphocytes, granulocytes, erythrocytes and kidney. In most patients deficiency of enzyme activity is associated with a mutation of the structural gene for PNP. The products of adenosine deaminase – inosine, deoxyinosine, guanosine and 2'-deoxyguanosine (dGuo) – are all naturally occurring substrates for the enzyme. The phosphorylase generates the corresponding purine bases, hypoxanthine or guanine (see Figure 1). Of the substrates that accumulate in excess in the absence of PNP activity, only dGuo can be salvaged directly by phosphorylation to the corresponding nucleotide, 2'-deoxyguanosine monophosphate. Phosphorylation is exclusively by deoxycytidine kinase which results in the accumulation ultimately of deoxyGTP.

Deoxyguanosine metabolism and T lymphocyte ontogeny

An understanding of the toxicity of dGuo in T cells may be derived from knowledge of the distribution of the enzymes important in nucleoside metabolism in different lymphocyte subpopulations and at different stages of maturation. The critical enzymes are adenosine deaminase, PNP and deoxycytidine kinase (Figure 1). The more immature the T cell, the higher the levels of adenosine deaminase and deoxycytidine

kinase and the lower the levels of PNP. Thus immature T cells are at risk for accumulating deoxyGTP.

Deoxyguanosine toxicity

Deoxyguanosine has long been recognized as a potent cytotoxic agent to cultured mammalian cells. Deoxycytidine may reverse or antagonize dGuo toxicity. This toxicity or inhibition of DNA synthesis by dGuo appears to be mediated by deoxyGTP-mediated inhibition of the enzyme ribonucleotide reductase. This results in the intracellular depletion of the DNA substrate deoxyCTP and explains the reversal of the dGuo toxicity by deoxycytidine.

It is now clear that of the four nucleoside phosphorylase substrates, only dGuo can result in inhibition of lymphocyte growth. This was initially shown in phosphorylase-deficient S49 cell mutants. Deoxyguanosine-mediated inhibition of DNA synthesis has also been observed in mitogen-stimulated human and murine T cells. Inhibition of T suppressor cell function has also been observed in human and murine T cells *in vitro*. Following *in vivo* administration of dGuo, inhibition of the development of murine suppressor T cells has been demonstrated. Deoxyguanosine injections have been shown to abrogate T cell-mediated suppression of contact sensitivity. The enhanced capacity of thymocytes to accumulate significant amounts of deoxyGTP has been taken advantage of in other situations. On the basis that dGuo is selectively toxic to proliferating intrathymic lymphocytes, this drug has provided an efficient means of producing lymphocyte depletion in human or murine organ-cultured thymuses. Results show that dGuo treatment leads to selective depletion of the lymphoid cells while allowing survival and function of the stromal and epithelial elements. In recent studies, the toxic effects of dGuo on T cell function in the presence of PNP activity may also be related, to some degree, to the accumulation of GTP. Proliferating lymphocytes exhibit sensitivity to intracellular GTP as well as dGTP.

DERMATOLOGICAL INFECTIONS

Edward T Ryan and Morton N Swartz, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts, USA

Normal skin provides an effective defense against most infectious agents. Keratinization, skin shedding, basal cell regeneration, lipid composition, low moisture content and the presence of a 'normal' cutaneous flora all contribute to making intact skin an efficient nonspecific barrier to invasion by most infectious organisms. The capacity of skin to mount a targeted immunologic response against individual invading microorganisms also makes skin an efficient specific barrier to most infectious agents. Bone marrow-derived Langerhans dendritic cells migrate throughout the epidermis, comprise 2–8% of all cells in the epithelium, sample antigen, and proceed through the dermis to regional lymph nodes via lymphatics. These cells express major histocompatibility complex (MHC) class II molecules and efficiently process and present antigens to CD4 T cells both locally (in the epidermis and dermis) and distally (in local lymph nodes). Memory/effector (predominantly CD45 RA⁺/RO⁺) T cells, natural killer cells and rare plasma cells are also scattered throughout dermatological structures. Normal skin cells such as keratinocytes, dermal fibroblasts and melanocytes are able to synthesize and secrete transforming growth factors α and β , tumor necrosis factor α , chemotactic and colony-stimulating factors and immunomodulatory cytokines such as interleukin 1 (IL-1), IL-3, IL-6, IL-8 and IL-10. Skin is therefore able to respond to invading microorganisms by directly recruiting and activating T cells and also by modifying dermal

endothelial cells to express molecules such as E-selectin that locally recruit additional cells of the immune system. Such cells themselves in turn affect keratinocytic proliferation, MHC expression and immunomodulatory factor secretion. This complex interaction results in an immune response that is locally directed and carefully tailored to respond to the specific microorganism of interest. It also means that the development of an appropriate dermatological immune response is as dependent upon the immunological capabilities and repertoire of the host, as it is upon the identity and nature of the infecting organism.

In normal skin, extracellular bacteria usually elicit a polymorphonuclear inflammatory response; intracellular bacteria, fungi and protozoa usually elicit a mononuclear immunologic response; and helminthic and ectoparasitic infections usually elicit an eosinophilic and immunoglobulin E (IgE)-mediated immunologic response (Table 1). Still other microorganisms are able to infect human skin while inducing only mild or minimal apparent immunologic changes.

Infections characterized by a minimal or moderate immunologic response

Human papillomaviruses (HPVs) are double-stranded DNA viruses that infect basal epithelial cells. HPVs can be divided into at least 65 genotypes.

Table 1 Skin disorders and their causative organisms

Disorder	Infecting organism
Skin infections characterized by a mild or minimal immunologic response	
Verruca vulgaris	Human papillomavirus
Molluscum contagiosum	Molluscum contagiosum poxvirus
Erythrasma	<i>Corynebacterium minutissimum</i>
Tinea versicolor	<i>Malassezia furfur</i>
Cryptococcosis	<i>Cryptococcus neoformans</i>
Cysticercosis (viable larvae)	<i>Cysticercus cellulosae</i> (larval stage of <i>Taenia solium</i>)
Follicle mites	<i>Demodex folliculorum</i>
Skin infections characterized by a polymorphonuclear inflammatory response	
Impetigo	Group A streptococci, and others
Bullous impetigo	<i>Staphylococcus aureus</i>
Ecthyma	<i>Streptococcus</i> spp., <i>Pseudomonas</i> spp. and others
Erysipelas	<i>Streptococcus</i> spp.
Cellulitis	Many bacterial species (e.g. <i>Staphylococcus</i> spp., <i>Streptococcus</i> spp., <i>Clostridium</i> spp., <i>Vibrio</i> spp., <i>Aeromonas</i> spp., etc.)
Folliculitis (including furuncles and carbuncles)	<i>Staphylococcus aureus</i> and others, including <i>Pseudomonas aeruginosa</i>
Candidiasis	Various <i>Candida</i> spp.
Skin infections characterized by an eosinophil IgE-mediated immunologic response	
Scabies	<i>Sarcoptes scabiei</i>
Onchocerciasis	<i>Onchocerca volvulus</i>
Cutaneous larva migrans	Various nonhuman hookworm species (e.g. <i>Ancylostoma braziliense</i> , <i>A. caninum</i>)
Cercarial dermatitis	Nonhuman schistosomal (e.g. avian) cercariae
Skin infections characterized by the presence of a monocyte/macrophage immunologic response	
<i>Diffuse histiocytic</i>	
Lepromatous leprosy	<i>Mycobacterium leprae</i>
Diffuse cutaneous leishmaniasis	<i>Leishmania</i> spp.
<i>Granulomatous</i>	
Tuberculoid leprosy	<i>M. leprae</i>
Cutaneous tuberculosis	<i>M. tuberculosis</i>
Leishmania recidivans	<i>Leishmania</i> spp. (usually <i>L. tropica</i>)
Tertiary syphilis (gumma)	<i>Treponema pallidum</i>
Dermatomycoses due to primary invasive systemic fungi	Various fungal spp. (e.g. <i>Blastomyces dermatitidis</i> , <i>Histoplasma capsulatum</i> , <i>Sporothrix schenckii</i>)

A nongenital HPV lesion of the skin is usually caused by HPV-1, 2, 3 or 4. In its most common manifestation, HPV infection of the skin presents as verruca vulgaris, the common wart. The immunologic response to HPV infection is poorly understood. A cellular response is undoubtedly important in preventing or limiting infection since individuals deficient in cell-mediated immunity are not only predisposed to HPV infection and dissemination, but also HPV infections in such individuals are often refractory to treatment. Additionally, patients with epidermodysplasia verruciformis, who are congenitally susceptible to disseminated HPV infection of the skin, appear to have a specific defect in cell-mediated immunity. Although affected individuals are not predisposed to infectious processes in general, T cell and natural killer cell responses directed against HPV-encoded antigens have been shown to be defective *in vitro* in such patients. The successful use of the cellular immunity-boosting glycoprotein interferon α in the treatment of HPV-infected individuals also suggests the importance of cell-mediated immunity in controlling HPV infections of the skin.

Even in normal individuals, verruca vulgaris induces minimal inflammatory changes and can persist for months or years. Histopathologic examination of involved skin can disclose an acanthoid dermis with papillomatosis, hyperkeratosis and parakeratosis. Despite the fact that viral HPV DNA and antigens are easily detected in many epithelial cells, a host immune inflammatory response is usually minimal (a mild mononuclear infiltrate may be present) or absent.

Tinea versicolor is another dermatological infection that elicits only minimal apparent immunologic change. The scaly hypo- or hyperpigmented macules of tinea versicolor are caused by the dimorphic, lipophilic fungus *Malassezia furfur* (formerly designated *Pityrosporum orbiculare*). Since the organism is part of the normal skin flora, it is unclear what allows the fungus to cause clinical disease. Defects or alterations in cellular immunity probably play a central role. Histopathological examination of involved skin demonstrates proliferating *M. furfur* organisms in stratum corneum with only minimal, if any, immunological infiltrate.

Infections characterized by a polymorphonuclear immunological response

The majority of 'classic' skin and soft tissue infections are due to extracellular bacteria and are characterized by the presence of a polymorphonuclear inflammatory response. Impetigo, ecthyma, erysip-

elas, cellulitis, folliculitis and furunculosis are examples of such common infections. Recruitment, activation and functionality of polymorphonuclear cells in infected skin is dependent upon the correct production of chemokines and interleukins such as IL-8, the proper display of surface integrin molecules by polymorphonuclear cells, the upregulation of endothelial cell counter-integrin receptor molecules such as intercellular adhesion molecule 1 (ICAM-1), the presence in polymorphonuclear cells of normal phagocytic and enzymatic capabilities, and a preserved ability of polymorphonuclear cells to degranulate.

Impetigo results from a superficial infection of skin, usually by group A streptococci or *Staphylococcus aureus*. Infectious manifestations begin with formation of thin-roofed vesicles that rapidly pustulate and rupture. Dried, purulent discharge results in the formation of a characteristic, adherent, golden-brown crust. The vesico-pustule forms between the stratum corneum and the stratum granulosum, and the inflammatory response is predominately polymorphonuclear in nature. The most serious complication is that of streptococcus-specific antibody-associated glomerulonephritis that can occur approximately 2 weeks after the cutaneous infection. Bullous impetigo also results from a superficial infection of skin but is caused by locally invasive phage-group 2 *S. aureus* that produces a toxin, exfoliatin. The action of this toxin results in the formation of bullae that contain *S. aureus* organisms and many polymorphonuclear cells. Bullous impetigo is not associated with the development of glomerulonephritis.

Erysipelas is a superficial cellulitis of skin and is most frequently caused by group A streptococci. Involved skin is usually red or brawny and is markedly indurated. The classic skin lesion rapidly expands peripherally. Edema is usually marked. Vesicles, bullae and petechiae may follow in involved skin. The patient may be febrile and systemically ill. Histopathologic examination of involved skin discloses marked vascular dilatation, extensive edema, and prominent infiltration by invading streptococci, especially of dermal lymphatic vessels. A polymorphonuclear cell infiltrate predominates.

Cellulitis is an acute, spreading infection of the deeper dermis and subcutaneous tissue and is most frequently caused by staphylococcal or streptococcal species. Infections with many other bacterial and fungal species have, however, been documented. The organisms proliferate in dermal and subcutaneous structures, and infection imparts an edematous, erythematous, inflamed appearance to involved skin. The advancing margin is less distinct than that seen

with erysipelas. Leukocytosis, regional lymphadenopathy, local abscess formation and bacteremia can complicate the infectious process. The dermatological response is predominantly polymorphonuclear in nature.

Folliculitis is an infection of hair structures. Although most cases are due to gram-positive organism such as *S. aureus*, gram-negative bacteria such as *Pseudomonas aeruginosa* and fungal species can also be causative agents. Superficial folliculitis is characterized by pustule formation at the follicular opening. Deep folliculitis can manifest as a furuncle, or boil; or as a carbuncle, with extensive deep pustular involvement of the dermis and deeper structures. A polymorphonuclear cell infiltrate predominates in both superficial and deep folliculitis. Deep folliculitis can be complicated by fever, leukocytosis, bacteremia, local abscess formation, sinus tract formation and local tissue necrosis.

Individuals with defects in polymorphonuclear cell recruitment or functionality often have recurrent and chronic infections of the skin. For example, individuals with chronic granulomatous disease (CGD) are deficient in activity of the multicomponent cellular enzyme NADPH oxidase and are predisposed to skin infections with catalase-positive organisms such as *S. aureus* which are often chronic and recurrent. NADPH oxidase is crucial in generating the oxidative burst required to kill many catalase-positive bacteria, and a deficiency in the activity of NADPH oxidase often necessitates a compensatory host response that is granulomatous in nature.

Infections characterized by an eosinophilic, IgE-mediated immunologic response

Certain skin infections provoke an immunologic response in which eosinophils, mast cells, basophils and IgE antibody-mediated reactions play prominent roles. Such responses are often orchestrated by activated T cells and the production of interleukins such as IL-4 and IL-5. Involvement of the skin by the microfilarial stage of *Onchocerca volvulus* results in such a response. Onchocerciasis is caused by the filarial nematode *O. volvulus*. Infective larval stages of the worm are inoculated into human skin during a blood meal of an infected *Simulium* blackfly. After migration and maturation of larvae, adult worms become localized in palpable subcutaneous nodules, onchocercomata. Female worms release millions of microfilariae that freely infiltrate the skin and subcutaneous tissues. Involvement of ocular structures can cause keratitis and blindness. Microfilarial involvement of the skin results in significant dermatitis and

pruritis. Histopathologic examination of involved skin discloses an eosinophilic infiltrate with extensive extracellular deposition of eosinophil granule proteins. An eosinophilic response in the blood is common. Longstanding infection of skin results in hyper- or hypopigmentary changes, lichenification, skin atrophy and loss of skin elasticity.

An eosinophilic immunologic response is also seen during infection of human skin by the scabies mite, *Sarcoptes scabiei*. During infection, the female mite burrows through the epidermal cornified layer and deposits eggs and feces. These antigens provoke an immunologic response that results in skin lesions that may be papular, vesicopapular, nodular or diffuse (crusted Norwegian scabies). Although the mites and their products do not penetrate below the epidermis, they provoke a prominent dermal perivascular inflammatory response containing lymphocytes, histiocytes and numerous eosinophils. Diffuse dermal infiltration by eosinophils is not uncommon. The increased propensity of patients coinfecting with *S. scabiei* and human immunodeficiency virus 1 (HIV-1) to have diffuse scabetic involvement of the skin, highlights the importance of cellular immunity in orchestrating an appropriate eosinophilic and IgE-mediated antibody response.

Infections characterized by a lymphocytic immunologic response

T cell-mediated immunity is critical in orchestrating and effecting the immune response, and the presence of T cells in skin can be demonstrated in almost all dermatological infections. Although humoral responses may play a pivotal role in the dermatological manifestations of many infectious processes (measles, for example), a dermatological response characterized by the presence of antibody-producing B cells or plasma cells in skin is rare. Dermal involvement during primary syphilis, however, is one such example. A primary syphilitic chancre develops at the site of skin penetration by the spirochete *Treponema pallidum*. The chancre is usually 1–2 cm in size with regular, raised, indurated, sharply defined borders. The lesion is classically painless and resolves within 1–2 weeks with treatment, or 3–6 weeks without therapy. Late manifestations of secondary or tertiary syphilis can occur if the infection is not appropriately treated. Histopathological examination of a primary syphilitic chancre discloses lymphocytic infiltration of the epidermis surrounding the ulcer margin. Cross-sectional examination of the ulcer bed discloses a dense dermal infiltrate that contains many plasma cells and lymphocytes. There is endothelial cell proliferation and swelling, and spirochetes can

be demonstrated throughout the epidermal and dermal areas. Despite this plasma cell response, and despite a rapid increase in serum *T. pallidum*-specific antibodies, cellular immunity undoubtedly plays a critical, and probably pivotal, role in controlling the syphilitic infection.

Infections characterized by a histiocytic immunologic response

There are many skin infections that provoke an immunologic response in which cells of the monocyte/macrophage lineage cells play critical roles. Dermatological immune responses in which macrophages appear to play a central role, however, can be divided into those in which a diffuse histiocytic pattern is present in skin and those in which frank granulomas are present. Some infectious agents are able to elicit a variety of histiocytic responses; a result largely due to differences in incompletely understood host factors. An example of one such infectious agent is *Mycobacterium leprae*, the causative agent of leprosy. Many individuals are resistant to becoming infected with *M. leprae*. Susceptible individuals who do become chronically infected can present with clinical symptoms and signs located anywhere on a continuum of disease whose extremes are referred to as 'tuberculoid' or 'lepromatous' leprosy. Disease in many individuals is manifest somewhere between these two extremes, so-called 'borderline' leprosy. Borderline involvement tends to be clinically 'unstable' and usually progresses toward one immunologic extreme or the other.

Tuberculoid leprosy is characterized by the presence in skin of a single or a few discrete macules or plaques. Such lesions are dry, erythematous or hypopigmented, and hypo- or anesthetic. Histopathologic examination of involved skin discloses granuloma formation with well-differentiated macrophages surrounded by lymphocytes. Many CD4⁺ helper T cells are present and there is prominent production of IL-2. The granuloma is usually surrounded by CD8⁺ cytotoxic and suppressor T cells. Granulomas often involve nerves. Caseation may be present, and bacilli are either absent or extremely rare.

Patients with lepromatous leprosy have diffuse, systemic involvement by *M. leprae*. Examination of skin in early disease discloses symmetric, large, widespread, poorly defined macules. In such an early stage, sensation is usually intact. The skin takes on a diffuse, nodular character in later disease and neural enlargement can then be pronounced. Histopathologic examination of involved skin discloses a diffuse, foamy, histiocytic dermal infiltrate. Granulomas are either absent or disorganized. Non-

differentiated macrophages filled with large numbers of *M. leprae* predominate. Compared to what is found in tuberculous lesions, CD4⁺ helper T cells are less frequent and IL-2 production is much less pronounced. CD8⁺ cytotoxic suppressor T cells are scattered throughout the lesions and large numbers of *M. leprae* organisms are widely disseminated.

In summary, as would be expected from the wide-ranging nature of organisms that can infect dermatological structures, the skin must be able to mount an adequate, efficient and directed immunological response specifically tailored to an invading organism. Careful immunological surveillance of dermatological structures and complex interactions between skin and immune cells insure that most dermatological infections are appropriately handled through the action and intricacies of chemokines, cytokines, growth factors, antibodies and various effector cells.

DETERMINANT SPREADING

Kamal D Moudgil, David B Stevens and Eli E Sercarz, Department of Microbiology and Molecular Genetics, University of California, Los Angeles (UCLA), Los Angeles, California, USA

Definitions

'Determinant spreading' (or epitope spreading) describes an amplification phenomenon observed in inflammatory autoimmune disease in which the original T cell response diversifies through induction of T cells against additional autoantigenic determinants. The response to the initiating determinant is followed by 'intramolecular' spreading, activation of T cells specific for other, often previously cryptic or subdominant self determinants (defined below) within the same antigen during the course of chronic and progressive disease; 'intermolecular' spreading involves determinants on other unrelated self antigens.

A multideterminant protein antigen possesses dominant, subdominant and cryptic T cell determinants. The dominant determinants are those that are most efficiently processed and presented from native antigen, whereas cryptic determinants are inefficiently processed and/or presented, or not at all.

Therefore, a response to a cryptic determinant can only be induced by immunization with the appropriate peptide which usually does not need additional processing. The subdominant determinants lie on the continuum between these two categories.

Examples of determinant spreading

Determinant spreading during the course of experimental autoimmune encephalomyelitis

The term, determinant spreading, was first applied by Lehmann and colleagues to the phenomenon observed in experimental autoimmune encephalomyelitis (EAE), a model of human multiple sclerosis (MS). EAE is an inflammatory demyelinating disease of the central nervous system mediated by CD4⁺ T cells specific for myelin autoantigens. EAE can be induced in susceptible mouse strains by immunization with myelin basic protein (MBP) or a peptide containing its dominant determinant, Ac1-11, or with proteolipid protein (PLP).

EAE in (B10.PL $\times$ SJL/J)F1 mice manifests as an acute disease phase followed by a chronic phase. Lehmann and coworkers induced EAE in (B10.PL $\times$ SJL/J)F1 mice by injection of MBP-dominant determinant peptide, Ac1-11, and observed that in the acute phase of the disease the T cell response was directed against Ac1-11, whereas in the chronic phase the response spread to cryptic determinants of MBP (35–47, 81–100 and 121–140). McCarron and colleagues also observed T cell reactivity to the large 89–169 fragment of MBP in mice immunized with MBP 1–37. T cell reactivity to these two fragments was restricted by different major histocompatibility complex (MHC) class II elements. Perry and coworkers observed that following induction of EAE in (SJL/J $\times$ PL/J)F1 mice by MBP immunization, T cell responses spread to PLP. Raine's and Miller's laboratories have shown that in EAE initiated in the SJL/J mouse by adoptive transfer of T cells reactive with the dominant determinant of MBP, responses spread to the dominant determinant, 139–151, of PLP. Miller's group went on to demonstrate intermolecular spreading between PLP 139–151 and PLP 178–191. Moreover, both groups demonstrated that T cells specific for the new determinants were functionally capable of causing EAE in naive recipient mice by adoptive transfer. Tuohy's laboratory has reported that in EAE in (SWR $\times$ SJL/J)F1 mice, there is a predictable, orderly determinant spreading involving PLP, MBP and myelin oligodendrocyte glycoprotein (MOG).

Intramolecular and intermolecular spreading in a spontaneous disease: insulin-dependent diabetes mellitus (IDDM)

During the very early phase of disease in the non-obese diabetic (NOD) mouse, T cell proliferative responses arise first to certain determinants on glutamic acid decarboxylase (GAD). Subsequently, a spreading of T cell responsiveness occurs to other determinants of GAD as well as to other unrelated antigens present in the β cells of the pancreatic islets (65 kDa heat shock protein, carboxypeptidase H, insulin, etc.). It is still unclear whether GAD is the endogenous initiator molecule, or whether some other proinflammatory event precedes this induction, to ignite a multidimensional conflagration. Interestingly, induction of intravenous or inhalation tolerance to GAD was successful in preventing insulinitis as well as clinical diabetes.

Diversification of T cell response can lead to engaging regulatory T cells: autoimmune arthritis

Adjuvant arthritis (AA) can be induced in the Lewis rat by injection of *Mycobacterium tuberculosis*, and

it serves as an experimental model for human rheumatoid arthritis (RA). T cell responses to the 65 kDa mycobacterial heat shock protein (Bhsp65) have been implicated in the pathogenesis of AA as well as RA. Moudgil and colleagues observed that in the acute phase of AA, T cell responses arise to several dominant and subdominant determinants of Bhsp65. Interestingly, in the late phase of AA, there was evidence for 'diversification' (broadening of responses to new determinants within an antigen after priming with the whole multideterminant antigen) of the T cell responses to certain additional determinants located at the C-terminal end of Bhsp65. Moreover, arthritic rats in the late phase of AA also raised vigorous responses to the corresponding C-terminal determinants within self(rat) hsp65 (Rhsp65). These results suggest that the observed diversification is possibly triggered *in vivo* by induction of Rhsp65-reactive T cells, and that it is critical in regulating acute inflammatory arthritis in the Lewis rat.

Reciprocal T and B cell spreading: systemic lupus erythematosus

In the (NZB $\times$ NZW)F1 mouse model of systemic lupus erythematosus (SLE), Hahn's group has shown that three V-region peptides from a single prototype DNA-specific antibody, under the appropriate conditions, can either accelerate or delay disease significantly. The above effects were explained on the basis of activation of T cells by the peptide-presenting B cells, followed by a T cell induction of B cells displaying a cross-reactive peptide, continuing reciprocally in this manner. Interference with this reciprocal expansion and/or associated regulatory (T_H1/T_H2) interactions could lead to protection. Similarly, both intramolecular and intermolecular immunoglobulin epitope spreading has been reported by Harley's group.

Breaking of self tolerance by raising a B cell response to a foreign homologous protein

Mamula and Janeway have shown that although mice are tolerant at the T cell level to self cytochrome *c* (cyt *c*), coimmunization with human and mouse cyt *c* breaks T cell tolerance to cryptic determinant region 1–80 of self cyt *c*. It was suggested that the foreign cyt *c* induces B cells that are cross-reactive with self cyt *c*; these B cells then bind, process, and present the self molecule to T cells.

Mechanisms of determinant spreading

Several mechanisms of determinant spreading have been proposed. 1) In the case of EAE and diabetes, upregulation of antigen processing and MHC presen-

tation in the local inflammatory milieu at the site of tissue damage may be responsible for the enhanced visibility of previously poorly displayed, cryptic and weak subdominant determinants. Although spreading will usually occur in a T_H1 proinflammatory context, T_H2 cytokines may also activate the B cell spreading mechanism. 2) B cells present antigen differently than conventional antigen-presenting cells (APCs) when they internalize antigen via their antigen-specific immunoglobulin (Ig) receptors. Celada's and Lanzavecchia's groups have shown that, depending upon what portion of the antigenic molecule is bound by the Ig receptor, different T cell determinants on the molecule will be preferentially presented in association with MHC class II molecules by the B cell. Similarly, processing and presentation of certain T cell epitopes could either be enhanced or suppressed when antigen (Ag) is internalized into APCs as Ag-Ig complexes via Fc receptors. 3) Increased internalization of a cell surface molecule as a result of its cross-linking by specific ligands may result in enhanced processing and presentation of previously cryptic determinants within that molecule. 4) In addition, other factors, such as infection of APCs with viruses or intracellular parasites, or the cellular stress response (heat shock response), should be considered as mechanisms that may alter antigen presentation schemes and the hierarchy of determinant display.

Implications of determinant spreading for immunotherapy

Knowledge about the temporal pattern of appearance of new T cell specificities directed against determinants within the same or different antigens is crucial in designing appropriate therapeutic strategies. Therapeutic approaches based primarily on controlling T cell responses to the initial disease-inducing determinant may not succeed if spreading of response has already occurred. Tolerance induction with peptides comprising encephalitogenic determinants appearing later in the disease may prevent subsequent progression of EAE. Recently, new strategies based on blocking the B7.1-CD28 interaction have been successful in blocking determinant spreading and thereby preventing relapses during the course of EAE. In the case of diabetes in the NOD mice, in which responses to several antigens appear in a hierarchical fashion, administration of GAD to young NOD mice has been successful in preventing the development of clinical disease. Some evidence in the EAE system points to the need for continued activity of the inflammatory T cells directed against the initiating determinant for perpetuation of the

spread. Removal or deactivation of the initiating cell, even after determinant spreading has begun, may weaken or eliminate disease progression. Therefore, measures directed to such initiating cells may be therapeutic despite their late administration.

DIAPEDESIS

Henry Beekhuizen and Ralph van Furth, Department of Infectious Diseases, University Hospital, Leiden, The Netherlands

Diapedesis is defined in immunology as the outward passage of cells through the intact vessel wall. The most prominent cells to traverse the endothelial cell lining of the vessel walls are blood leukocytes, but tumor cells also translocate via the blood circulation through diapedesis from the primary tumor sites to distant sites in the body. Diapedesis of leukocytes is a major event in the migration of leukocytes from the blood circulation to sites of inflammation or tissue injury and in the recirculation of lymphocytes from the blood to the lymphatic compartment. Diapedesis of leukocytes is often confused with the terms 'leukocyte transmigration' or 'leukocyte extravasation'. These terms define the entire process of leukocyte migration from the blood circulation to the extravascular connective tissue, across the vessel wall endothelium. Diapedesis is regarded as the final event in the transmigration, i.e. the actual penetration of the vascular endothelium and the subendothelial matrix.

Diapedesis: the final chapter in a sequence of separate consecutive adhesion events

Elegant intravital microscopy studies revealed that diapedesis of leukocytes is preceded by a coordinated sequence of adhesion events that enables these cells to withstand the hemodynamic forces, known as shear forces, generated by the flow of blood and to make firm contact with the vascular endothelial cells.

At present, three separate consecutive events have been clearly distinguished (Figure 1). Leukocytes first attach to the vessel wall in a rolling interaction (1) and then are arrested, sticking firmly to the surface membrane of a single endothelial cell (2), before diapedesis (3). Specific cell surface glycoproteins on endothelial cells and leukocytes are directly implicated in these events.

1. Leukocyte rolling

The rolling of leukocytes along the endothelial lining of small venules is observed exclusively at inflammatory sites or sites of vascular injury. Leukocyte rolling is a process involving attachment to, and detachment from, the endothelium. Consequently the leukocytes slow down in the main vascular flow. Studies in rodents and *in vitro* experiments using laminar flow chambers showed that leukocyte rolling is initiated by the expression of specific molecules, designated as selectins, on the surface of leukocytes, i.e. L-selectin (CD62L), or activated endothelial cells, i.e. P-selectin (CD62P) and E-selectin (CD62E). The amino-terminal lectin domain of these adhesion molecules recognizes sialyl Lewis^x (CD15s) or related sulfated, fucosylated or sialylated carbohydrate structures on the opposing cell and is thus critically involved in cell–cell adhesion. Selectin-mediated rolling is an obligatory event before leukocytes can move on to the stage of firm adhesion.

Figure 1 Consecutive events in the binding and transendothelial migration of leukocytes. (1) Rolling of leukocytes along the endothelium of vessel wall adjacent to an extravascular site of inflammation. (2) Arrest of rolling and firm attachment of leukocytes to the endothelial cells. (3) Lateral migration of leukocytes over the surface of the endothelial cells and subsequent diapedesis. Shear forces generated by the flow of blood, chemokines and adhesion molecules belonging to the family of selectins, immunoglobulins and integrins act in sequence, with some overlap.

2. Arrest of rolling and firm adhesion

The arrest of rolling leukocytes at a particular site of the vascular endothelium involves cell surface adhesion molecules that are different from those required for rolling. At least five heterodimeric cell surface proteins, designated as integrins, have been implicated in the firm adhesion of leukocytes to endothelial cells. These proteins are: LFA-1 (lymphocyte-function associated antigen 1; CD11a/CD18); CR3 (complement receptor 3; CD11b/CD18) and p150,95 (CD11c/CD18), which belong to the β_2 subclass of the integrin superfamily of adhesion molecules; the β_1 -integrin VLA-4 (very late antigen-4; CD49d/CD29); and the β_7 -integrin LPAM-1 (lymphocyte Peyer's patch adhesion molecule 1; CD49d/ β_7). These integrins bind their respective counterstructure on the endothelial surface, which include proteins that structurally belong to the immunoglobulin supergene family, i.e. ICAM-1 (intercellular adhesion molecule 1; CD54), ICAM-2 (CD102) and VCAM-1 (vascular cell adhesion molecule 1; CD106). Most of the adhesion promoting molecules are expressed on the surface of endothelial cells at inflammatory sites and are not or are minimally expressed on resting (nonstimulated) endothelial cells.

The integrin-mediated firm leukocyte-endothelium interaction is triggered or amplified by the action of chemotactic cytokines or chemokines, such as IL-8 (interleukin 8) or MCP-1 (monocyte chemotactic protein 1), that are produced by the endothelial cells in response to activation or binding of leukocytes. The present belief is that selectin-mediated rolling of leukocytes will enhance exposure to chemokines that

are bound to, and presented by, proteoglycan-like molecules on the surface of the endothelial cell. This will lead to activation of integrin adhesiveness and firm leukocyte adhesion to endothelium.

Firm adhesion between leukocytes and the endothelium coincides with an increase of the intercellular contact area. These leukocytes change shape, become flattened and move in a lateral direction over the endothelial cell surface. Very little is known about the exact mechanisms and molecules involved in this process, but there are some indications that after initial contact between leukocytes and endothelial cells ICAM-1 diffuses in the plane of the membrane of endothelial cells to the intercellular contact. Whether chemokines provide an additional stimulus is not yet clear.

3. Diapedesis: the actual transendothelial migration

Most endothelia form a continuous and nonfenestrated monolayer of endothelial cells. The peripheral membranes of adjacent endothelial cells overlap each other and at these sites, specialized junctions, e.g. tight and gap or communicating junctions, preserve the integrity of the monolayer. Adherent leukocytes cross the vessel wall by squeezing themselves between tightly apposed endothelial cells in an ameboid fashion. Transendothelial migration of leukocytes through the cytoplasmic compartment of the endothelial cells is not a normal pathway. During diapedesis the barrier function of the endothelium is excellently preserved because of the close interaction between the migrating leukocyte and the

peripheral membranes of the endothelial cells. The maintained integrity of the endothelium during diapedesis of leukocytes *in vitro* can be very well demonstrated by measuring the electrical resistance over the monolayer, which, in fact, does not change during diapedesis. Electron microscopy and time-lapse microcinematography have indicated that the retraction of endothelial cells is restricted to the endothelial cells which are directly involved in the interaction, and that most of the surrounding endothelial cells maintain their integrity and spreading morphology. Although reorganization of the cytoskeletal filaments must be involved, the exact mechanism of endothelial cell retraction, as well as the intracellular signal(s) which coordinate the opening of the interendothelial junctions, are still obscure. It is speculated that the interaction of leukocytes with the endothelial cell surface adhesion molecules is an important initiating signal.

Because leukocytes must adhere to the endothelium before subsequent diapedesis, it is difficult to unravel the contribution of a particular adhesion molecule to firm adhesion of leukocytes to the endothelium versus its role in the actual diapedesis. In experimental settings agents that inhibit firm adhesion will also reduce diapedesis. Clearly, β_2 -integrin molecules are involved in diapedesis. This is concluded from the profound lack of neutrophil and monocyte diapedesis observed in patients with the leukocyte adhesion deficiency (LAD) syndrome, who are genetically deficient in the functional expression of leukocyte β_2 -integrin molecules. Beside β_2 -integrins, other adhesion molecules contribute to the diapedesis. Recent experiments suggest a role for PECAM-1 (platelet-endothelial cell adhesion molecule-1; CD31). This molecule is expressed on leukocytes and it is found in high densities on endothelium at sites of intercellular junctions. An interesting feature is that PECAM-1 can interact with itself. It is suggested that such homophilic binding between PECAM-1 on leukocytes and PECAM-1 on endothelial cells may promote diapedesis, whereby the leukocyte migrates in the direction of the highest density of endothelial PECAM-1, a process called haptotaxis.

Following diapedesis the migrating leukocytes attach to and subsequently traverse the subendothelial matrix, or basement membrane, consisting of fibronectin, laminin, elastin and various types of collagen, and accumulate in the extravascular tissues. The endothelial cells rapidly reconstruct an intact monolayer of tightly connected cells. The time required for leukocytes to attach to and traverse the endothelium varies from several minutes to several hours, depending on the type of invading cell, the

type of endothelium including their basal matrix and the presence of (inflammatory) stimuli.

Diapedesis of leukocytes under noninflammatory conditions

Under normal circumstances the vascular wall, composed of a monolayer of endothelial cells sited on a basement membrane, does not promote the adherence and transendothelial migration of circulating leukocytes. The nonthrombogenic and nonhemostatic surface properties of the endothelium and the narrow spaces (varying from 10 to 200 nm) between adjacent endothelial cells normally prevent cellular adherence and subsequent diapedesis. Diapedesis of leukocytes under noninflammatory conditions is mainly restricted to specific sites, the high-endothelial venules, bearing high-walled endothelium, where recirculating lymphocytes migrate from the blood circulation to the lymphatic compartment.

Diapedesis of leukocytes under inflammatory conditions

At inflammatory sites or at sites of vascular injury, the adhesiveness of endothelial cells for leukocytes is increased and results in enhancement of the number of leukocytes traversing the endothelium and an invasion of the extravascular, inflamed, tissues. Both processes are regulated by the local generation and secretion of inflammatory mediators, which in turn regulate the expression of adhesion molecules on the surface of the cells involved. This can be mimicked by treatment of leukocytes or cultured endothelium, *in vitro*, with cytokines, such as IL-1 α , tumor necrosis factor α or interferon γ , or with chemoattractants such as anaphylatoxin C5a, leukotriene B₄, formylmethionyl peptides (e.g. fMLP) or chemokines (e.g. IL-8 or MCP-1). These studies revealed that expression of the various adhesion molecules on endothelial cells is often transient and depends on the type of stimulus. This is well illustrated in endothelial cells treated with the proinflammatory cytokine IL-1. Within a few minutes of activation these endothelial cells express high levels of P-selectin, which returns to basal levels within an hour; several hours after activation, surface expression of E-selectin is maximal, returning to basal levels within 1 day; about a day after activation, ICAM-1 and VCAM-1 expression reach relatively stable plateau levels. These changes in surface expression of endothelial adhesion molecules most likely correlates with the shift from granulocyte to monocyte and lymphocyte extravasation that is observed *in vivo* about 6–24 hours after the onset of inflammation.

Diapedesis and cell activation or cell differentiation

Close cellular interactions might have consequences for cellular activation and/or cell differentiation. Circulating monocytes and granulocytes traverse the endothelium as a response to a stimulus. In the tissues, monocytes differentiate into different types of macrophages. The exact trigger for the onset of such differentiation is unknown. It has been suggested that the cellular contact occurring during diapedesis provides a signal for differentiation. More likely, however, is that local conditions, which can be anatomical or biochemical, including cytokines or other mediators, and oxygen tension orchestrate monocyte differentiation. This is exemplified by differences between peritoneal macrophages, alveolar macrophages, Kupffer cells, osteoclasts, etc.

Experimental models

Observations on the behaviour of circulating leukocytes are difficult. However, techniques such as time-lapse and intravascular microscopy on rabbit ear, mesenteric tissue of mouse or rat, hamster cheek pouch or bat wing enabled us to monitor intravascular events and diapedesis. Radiolabeled blood cells (^{111}In or ^{92}Tc) are useful tools for studying the kinetics and clearance of cells from the blood circulation and for monitoring differences in cell distribution and extravasation to the distinct tissue compartments.

Unfortunately these methods offer little insight into the molecular mechanism(s) underlying cellular adherence and diapedesis. Progress in identifying the mechanisms involved has been dependent on the development of *in vitro* systems that not only permit the adherence of cells to endothelial cells but also allow these cells to penetrate and traverse the endothelial monolayer, including the underlying basement membrane. One approach involves the interaction of cells with monolayers of endothelial cells grown on nitrocellulose or polycarbonate filters. Biological membranes, such as the mesenteric membrane or amnionic membrane, or layers of cultured smooth

muscle cells also serve as excellent carriers for endothelial cells in this respect. The endothelial cells used for these *in vitro* studies are usually harvested from large vessels, as isolation and cultivation are fairly simple and do not require expensive equipment or advanced techniques. However, diapedesis of leukocytes *in vivo* is more prominent in capillaries, post-capillary venules and small venules than in macrovessels and occurs during constant blood flow. Therefore, during the past few years, there has been enormous interest in the isolation and culture of microvascular endothelial cells from distinct vascular sites and in the development of new techniques to study adhesion and subsequent diapedesis of leukocytes under flow conditions.

DIGEORGE SYNDROME

Anthony R Hayward and **David Manchester**, University of Colorado School of Medicine, Denver, Colorado, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

DiGeorge reported in 1965 the occurrence of thymic hypoplasia and hypoparathyroidism in infants with congenital heart disease. Reviews of DiGeorge syndrome in the 1970s described a diverse collection of phenotypic features that, a decade later, came to be understood as a developmental field defect, designated *DiGeorge sequence* (DGS), attributed to failed differentiation and migration of cephalic neural crest cells. Only a few cases were familial so the etiology was generally assumed to involve some environmental damage to the developing embryo. The most significant advance has been the identification of microdeletions on human chromosome 22q in most patients with DGS. Mapping and sequencing of genes on the affected area now promises a better understanding of the mechanisms responsible for the maldevelopment of the third and fourth pharyngeal pouches in DGS.

Genotype

Most affected individuals have deletions in the 22q11-qter region from one of their two copies of chromosome 22. These deletions are large, usually spanning at least 2 Mb. In about 20% of cases the deletion is visible when chromosomes are viewed at resolutions of 600 bands or greater. In most cases the deletions are most readily detected by molecular methods, such as commercially available locus-

specific fluorescence *in situ* hybridization (FISH) probes (Figure 1).

The chromosome 22q11 region is particularly rich in duplicated sequences which facilitate recombination and this may be the mechanism which allows for structural mutations such as deletions and duplications. In about 75% of sporadic cases of DGS, the affected chromosome is inherited from the mother. A recent survey found 5% of neonates with congenital heart disease had deletions at 22q11. These findings support an extrapolated prevalence of 22q11 microdeletions approaching 1:5000. Numerous families have been reported in which deletions passed through several generations causing dominantly inherited abnormal phenotypes including DGS.

The mechanism by which the chromosome 22q11-qter deletions cause the phenotypic features described below is not established. 'Haploinsufficiency' of genes which might be developmentally important in this region is one possibility and DGS has been considered a prototypic 'contiguous gene syndrome' involving an unknown number of genes. Alternatively, the phenotype may result from deletion of a single gene, as is suggested by the recent report of the complete DGS in association with a balanced translocation. A candidate gene disrupted by this translocation has been named HIRA because of homologies with the HIR1 and HIR2 repressors of

Figure 1 (A) Partial karyotype and ideogram depicting the deletion of bands q11.21 on a number 22 homologue, the microdeletion associated with DiGeorge/Velocardiofacial syndrome. (B) The deletion of the DiGeorge syndrome critical region (DSCR) detected by fluorescence *in situ* hybridization (FISH) using N-25 cosmid (Oncor, Inc.) (Courtesy of the Colorado Genetics Laboratory.)

histone gene transcription. Reports of the DiGeorge syndrome associated with mutations at loci other than 22q11 are accumulating. The most common alternative locus is chromosome 10p13 where, again, deletions producing haploinsufficiency have been documented.

Phenotype

An acronym CATCH 22 (for cardiac defects, abnormal face, thymic hypoplasia, cleft palate and hypocalcemia) has been proposed to describe the commonly affected structures in DGS (Figure 2). Reviews of DGS diagnosed clinically have generally emphasized the variability of each of these features, such that the most immunodeficient patients may have perfectly normal hearts. Even patients diagnosed with chromosome 22q11-qter deletions are phenotypically variable. Concurrence of two or more of the following probably suffices to make a clinical diagnosis of DGS: conotruncal heart defect, hypocalcemia, hypoplastic/absent thymus and typical facial dysmorphism (including small palpebral fissures, a 'beaked' or 'bulbous' nose and small or posteriorly rotated ears).

Features of DGS overlap with other malformations affecting the migration of cephalic neural crest cells. These include the velocardiofacial (VCF; Shprintzen) syndrome, the CHARGE association and various combinations of midline structural defects found in association with hypertelorism (e.g. Optiz-Frias syndrome, Kallmann syndrome). Thymic hypoplasia has also been reported with abnormalities of chromosome 10 and observed in fetuses exposed *in utero* to 13-*cis*-retinoic acid (Accutane®). In the mouse, a DGS phenocopy that includes thymic hypoplasia can be produced by recessive knockout of *hox 1.5* in transgenic embryos. There are no *hox* gene homologs known on human chromosome 22. The DGS pheno-

type is probably best considered a development field defect of heterogeneous etiology, even though it is most commonly encountered in association with chromosome 22q deletions.

The VCF syndrome (with cleft palate, lateral nasal build-up, mild microcephaly, congenital heart disease typically involving atrial or ventricular septal defects, and unusually long and tapering fingers) is also associated with chromosome 22q11 deletions. VCF syndrome patients usually have normal numbers of T cells and are not usually hypoparathyroid. They have a high frequency of otitis media and sinus infections, perhaps related to altered facial development, but the extent to which thymic hypoplasia contributes to this phenotype is unclear.

Individuals affected by chromosome 22q11-qter deletions with either the DGS or VCF phenotypes also share certain neurodevelopmental problems. Expressive aphasia is common and need not be associated with obvious intellectual retardation. When intellectual retardation is apparent, the contribution of expressive aphasia to this problem is incompletely understood. Anxiety and affective disorders also occur commonly and several cases with schizophrenia have been reported. Familial psychoses in some pedigrees have been linked to polymorphisms mapping to the chromosome 22q11-qter region.

Immunologic findings

Patients originally described with DGS had low proliferation of blood lymphocytes in response to the mitogen phytohemagglutinin (PHA). Affected children who died had no thymus in their anterior mediastinum, although some did have ectopic thymus tissue in the neck. Most subjects with DGS, diagnosed either by phenotype or by chromosome 22q11-qter microdeletions, have normal blood lymphocyte counts and normal absolute counts of CD3, CD4 and CD8 cells by 1 year of age. Their serum immunoglobulins are normal. In the first months of life the T cell counts are variable, with some having low absolute numbers of CD3 cells. The subjects who have normal numbers of T cells also appear to make good antibody responses to infections (such as chickenpox) and to immunizations with adjuvanted bacterial toxoids. Reduced responses to polysaccharide antigens in subjects who had low counts of CD4 cells in blood have been reported. A single subject with complete DGS had limited diversity of antibodies, a finding consistent with the known role of T cells in facilitating B cell proliferation and diversification.

A small number of DGS subjects, perhaps 2–5% of the total, have a chronically low number of circul-

Figure 2 DiGeorge phenotype. This affected infant has a dimpled nose and long philtrum of the upper lip.

ating T cells. These subjects seem to be vulnerable to a much more severe disorder characterized by the production of autoantibodies to blood components and/or clotting factors. There is also a clinical impression that these subjects have an increased frequency of upper respiratory tract infections.

Diagnosis

Any patient with two or more features suggesting DGS or VCF should be investigated for chromosome 22q11-qter deletions through high resolution chromosomal studies that include FISH probe analysis at the Shprintzen/DiGeorge locus. This is especially true for infants with conotruncal cardiac malformations. While less than 1% of infants with isolated tetralogy of Fallot are found to have microdeletions on chromosome 22q, more than 40% will be positive for a deletion when additional dysmorphic features are present. If a deletion is found, the parents' chromosomes should also be investigated, even when neither mother nor father appears to be affected. If a deletion is present in a parent the risk of a recurrence in a subsequent pregnancy approaches 50%. In the absence of a parental deletion, recurrence risks for DGS/VCF are low, but not negligible, due to the potential for parental gonadal mosaicism. Cytogenetic prenatal diagnosis should be offered in subsequent pregnancies regardless of parental karyotype. In cases lacking microdeletions, further investigation of parathyroid and thymic hypoplasia can be deferred in the absence of symptoms. In chromosomally normal cases involving congenital heart disease, subsequent pregnancies should be monitored by fetal ultrasonography and echocardiography.

Treatment

Infants with major cardiac defects require corrective or palliative surgery to survive. Blood used to transfuse these children should be irradiated or depleted of T cells (to avoid graft-versus-host disease) until the recipient is known to have functioning T cells. Patients with hypocalcemia may need intravenous calcium to control seizures or tetany, and subsequently most need both oral calcium supplements and vitamin D. By far the majority of affected infants develop normal numbers of T cells in the first 6 months of life and require no immunologic interventions. Those whose T cell numbers remain low and who have either recurrent infections or autoimmune disease are likely to be candidates for some form of immunologic intervention. Perhaps the least controversial is immunoglobulin G (IgG) treatment

for those with recurrent respiratory tract infections, particularly if their antibody responses are known to be impaired. Subjects who have HLA-matched siblings have been treated with blood transfusion and with bone marrow transplantation, with the assumption that sufficient mature T cells would be transferred to colonize the recipient. Although much has been written about fetal thymus transplantation in DiGeorge syndrome, most stems from the late 1960s and the 1970s, before the potential for spontaneous improvement in T cell numbers was appreciated. A few DGS cases with persistently low numbers of blood T cells have been grafted with pieces of child thymus, after these were first cultured *in vitro* to reduce the number of mature donor T lymphocytes. Clinical improvement has been reported in some, whether or not the thymus was matched with the recipient for histocompatibility antigens. The number of DGS patients treated by thymus transplant is still too small for systematic analysis.

DIVERSITY, GENERATION OF

Kathleen N Potter and **J Donald Capra**, Molecular Immunology Center, Department of Microbiology, University of Texas Southwestern Medical Center, Dallas, Texas, USA

Immunoglobulins (Ig) are four-chain glycoproteins composed of two identical heavy (H) and two identical light (L) chains forming a Y shaped molecule (Figure 1). Each chain is divided into a variable (V) domain and either one (light chain) or three or four (heavy chain) constant (C) domains. The tips of the two prongs consist of variable sequences while the remaining portion of the prongs and the stem contain sequences common to antibodies of the same isotype. Antigens are bound by Ig through the V domains, and are eliminated through the effector functions of the C domains. V domains are divided into framework regions (FR) and complementarity determining regions (CDR). Four FRs and three CDRs alternate to give the pattern FR1, CDR1, FR2, CDR2, FR3, CDR3, and FR4 (Figure 2). It is predominantly the three CDRs from the H chain, and the three CDRs from the L chain which contact antigen. The FR support the immunoglobulin β barrel structure, and have also been shown to influence antigenic specificity. The folding of a V_H and V_L domain is shown in Figure 3. The residue numbers

Figure 2 Structure of rearranged V_H and V_L domains. The relationship between the V(D)J gene segments and the framework and complementarity-determining regions is indicated. N segments have been identified at V_LJ_L junctions in about 20% of light chains.

corresponding to their FR and CDR positions are indicated in Table 1.

Immunoglobulins are produced by B lymphocytes either as membrane-bound receptors or secreted Ig. Each B cell produces immunoglobulins of identical specificity. It is necessary for the immune system to

Table 1 Amino acid residue numbers corresponding to positions in H and L chain variable domains

Region	Chain	Position
FR1	Heavy	1–30
	Light	1–23
CDR1	Heavy	31–35 (31a,b)
	Light	24–34 (27a–f)
FR2	Heavy	36–49
	Light	35–49
CDR2	Heavy	50–65 (52a–c)
	Light	50–65
FR3	Heavy	66–94 (82a–c)
	Light	66–88
CDR3	Heavy	95–102 (100a–k)
	Light	89–97 (95a–f)
FR4	Heavy	103–113
	Light	98–107 (106a)

CDR (complementarity-determining region), FR (framework region). The numbering system serves to optimally align conserved residues. Length variations are labeled with letters.

generate a population of B cells producing antibodies with a diverse array of antigen-combining sites in order to interact specifically with the myriad of antigenic structures which can invade a host. There are several mechanisms used for generating this diversity in the variable domains of human immunoglobulins. They include 1) the innate diversity in the sequences of the V (variable), D (diversity) and J (joining) gene segments, 2) site-specific DNA rearrangement of the

V, D and J gene segments, 3) deletion of nucleotides at joining regions by nucleases, 4) insertion of non-templated and templated nucleotides at joining regions, 5) fusion and inversion of D regions, 6) pairing of light and heavy chains, and 7) somatic hypermutation. The result of these mechanisms is the production of an estimated 10^{14} different antibodies in humans.

Human germline diversity

The production of a human immunoglobulin involves an ordered series of somatic DNA rearrangements involving gene segments (exons) located on three different chromosomes: the heavy (H) chain locus on chromosome 14, the kappa (κ) chain locus on chromosome 2, and the lambda (λ) chain locus on chromosome 22. The human immunoglobulin H chain locus is located on chromosome 14q32.3, and spans approximately 1100 kb. The entire V_H locus has been mapped and the V_{H1} genes sequenced. There are approximately 100 V_H gene segments, of which about only half are functional, approximately 30 D genes, and nine J_H genes, of which six are functional (Figure 4). At the protein level, V_H gene segments encode FR1, CDR1, FR2, CDR2 and FR3 (Figure 2). The 3' end of the V_{H1} , D and 5' end of the J_H gene segment form the CDR_H3, with the remainder of the J segment forming FR4. The V_H gene segments are grouped into seven V_H

Figure 4 Diversity generated by VDJ recombination. The organization of a portion of the human immunoglobulin heavy chain locus containing the V, D and J gene segments is shown. The numbers refer to total number of gene segments including pseudo-genes. The union of one D gene segment to one J_H gene segment occurs prior to one V gene segment joining to the -DJ_H pair. The leader intron is removed during RNA splicing. Alternative splicing can lead to either membrane bound (m) immunoglobulin, or secreted immunoglobulin (s). The approximate numbers of the gene segments are indicated. E_μ, enhancer; S_μ, μ switch region; μ_m, membrane-bound IgM; μ_s, secreted IgM. The primary repertoire consists of V(D)J recombinations in the absence of antigen, producing predominantly antibodies which are polyclonal but of low affinity. The secondary repertoire consists of antibodies selected from the primary repertoire by antigen. These antibodies are characterized by mutation and high affinity for specific antigens. (Reproduced with permission from Okada A and Alt FW (1995) The variable region gene assembly mechanism. In: Honjo T and Alt FW (eds) *Immunoglobulin Genes*. London: Academic Press.)

families based on greater than 80% homology at the nucleotide level (Table 2). In the human, the V_H family gene segments are interspersed as opposed to the mouse, where the V_H gene segments from particular families are clustered. There are four D_H clusters (D1–D4) each containing seven D_H segments. Two orphan V_H loci are located on chromosomes 15 and 16, some of which are potentially functional, although they are not associated with J_H or C region genes. At least four orphan D_H clusters, each con-

sisting of five D_H segments, are located on chromosome 15. There are approximately 76 (40 of which are functional) V_K gene segments (grouped into seven families), five J_K gene segments, approximately 50 (30 of which are functional) V_λ gene segments (grouped into nine families), and 7–10 J_λ gene segments. L Chain V domains are the product of V_L and J_L gene segment recombination. The junction between the V_L and C_L encodes the CDR_{1,3} (Figure 2).

The mouse V_H locus is located on chromosome 12. As with the human system, the V_H, D and J_H gene segments are arranged in separate clusters. The V_H gene segments are divided into 14 families based on nucleotide homology. A rough estimate of the number of V_H members is 100. On chromosome 12, members of one family tend to remain in groups and are not as interspersed as on the human chromosome. There are three families of murine D_H gene segments, and four J_H segments. There is evidence of J_H proximal usage of V_H gene segments, unlike in the human system where there is no evidence for position playing a role in V_H gene segment usage.

Table 2 Human V_H gene segments

Chromosome	V _H family							Total
	1	2	3	4	5	6	7	
14q32	14	4	48	12	2	1	6	87
15q11	6	0	1	1	0	0	0	8
16p11	4	1	11	0	0	0	0	16
Total	24	5	60	13	2	1	6	111

Approximately 50% of these gene segments are nonfunctional pseudogenes.

VDJ combinatorial diversity

Both H and L chain V domains are the product of somatically rearranged V, D (H chain only), and J gene segments, a process specific to lymphocytes. During rearrangement, only one of each type of segment is used. The mixing and matching of gene segments is a main contributor to the generation of a diverse repertoire of antibodies. The result of the recombination event is that three gene segments, which originally were scattered over several kilobases of DNA, are brought together to form a single gene which can then be transcribed and translated. In H chain assembly, V_HDJ_H rearrangement proceeds initially as a $-DJ_H$ rearrangement on both chromosomes in pro-B cells, followed by V_H to $-DJ_H$ on one chromosome in pre-B cells (Figure 4). If that rearrangement is nonproductive (i.e. results in a frameshift), rearrangement occurs on the other chromosome. The production of the μ H chain on the cell surface, in association with surrogate L chains, inhibits further H chain VDJ rearrangements (allelic exclusion), and induces the rearrangement of V_L and J_L gene segments. In general, rearrangement is attempted first at the κ locus, and if rearrangement on the two chromosomes are nonproductive, rearrangement is initiated at the λ locus. Functional rearrangement of an L chain stops further rearrangements of L chain genes of the same isotype (allelic exclusion). Each V and J gene segment has only one correct reading frame. D segments can theoretically be read in all three reading frames in different VDJ recombinations, which contributes to antibody diversity. Since there does not appear to be a mechanism regulating the alignment of V and J gene segments, productive (inframe) joining is accomplished in one out of every three joining events.

The process of V(D)J recombination is site-specific, and involves the enzymatic cutting and ligating of DNA. It is directed by recombination signal sequences (RSSs) adjacent to the DNA segments to be joined. RSSs consist of a conserved heptamer and nonamer separated by a spacer of either 12 or 23 base pairs (Figure 5). The consensus palindromic heptamer sequence is CACAGTG and the consensus nonamer sequence is ACAAAAACC. It is always the heptamer which is directly adjacent to the gene segment. RSSs are only on the 3' side of V_H and V_L gene segments, and have 23 base pair spacers. RSSs are only on the 5' side of J_H , J_κ and J_λ gene segments, and have 23 base pair spacers. D gene segments, which are only in the H chain locus, are flanked by RSSs having 12 base pair spacers. Recombination occurs almost exclusively between two signals of 12

and 23 spacer lengths. This is referred to as the '12/23 rule'.

V_HDJ_H recombination between RSSs is characterized by biases. Forty-six out of 87 mapped V_H segments have been shown to be used. Using D- J_H minilocus substrates, it was determined that the sequence of the signal and coding ends determines the bias. The spacer sequences, and the sequences adjacent to the RSSs are not conserved. The nucleotide composition of the three residues of the heptamer closest to the cleavage site can affect the efficiency of recombination. There is no evidence of a correlation between preferential rearrangement of a V_H gene segment and its position in the V_H locus. It is thought that V(D)J rearrangements are dependent on the accessibility of a locus for the recombination machinery. Transcription may be involved as germline V and J-C transcripts are found prior to the onset of DNA recombination.

During V(D)J rearrangement, double-strand breaks are introduced at heptamer borders which most often religate head-to-head forming a signal joint, and the coding ends next to the heptamers are joined to form a coding joint (Figure 5). If the two RSSs are in the same orientation, the intervening segment is inverted and maintained in the chromosome (inversional rearrangement). If the two RSSs face the opposite orientation, the intervening segment is deleted (deletional rearrangement) (Figure 6). Excised circular DNA is not known to have a function. D- J_H joining predominantly undergoes deletional joining using the J_H proximal RSSs of the D gene segment. V_HDJ_H chain recombinations most often result in the deletion of the intervening DNA, while in many κ chain segments, recombination occurs by inversional joining. Occasionally recombination results in an exchange of RSSs between two gene segments resulting in a hybrid junction. Junctional modifications can involve complex rearrangements including V-D-D-J, V-D-inverted D-J, etc. to generate different CDR_{H3} sequences. Some of these unusual rearrangements break the 12/23 rule.

N-Segment and P-nucleotide additions

During V(D)J recombination, the cleavage of the two heptamer elements generates blunt ends, which are unmodified during ligation to form a heptamer-to-heptamer signal joint. Coding junctions, however, are heterogeneous in sequence. The recombination process creates many different coding junctions from the same RSS pairs. Nucleotides can be either removed or added enzymatically. Exonucleases can delete residues, while nucleotides can be added at junctions by two different mechanisms. These are

Figure 5 Formation of coding and signal joints. Heptamer fusion leads to an unmodified signal joint, and hairpin formation followed by exonuclease deletion and N and P nucleotide addition leads to a modified coding joint. (Reproduced with permission from Okada A and Alt FW (1995) The variable region gene assembly mechanism. In: Honjo T and Alt FW (eds) *Immunoglobulin Genes*. London: Academic Press.)

referred to as N-segment and palindromic (P)-nucleotide additions. N-Segment diversity results from the addition of untemplated bases by terminal deoxynucleotidyl transferase (TdT). TdT activity is minimal in the fetus and neonate but is upregulated postnatally. As a result, the CDR_H3 is shorter in the fetal compared with the adult repertoire. While TdT appears to act predominantly on H chains, N segments have been identified at L chain VJ junctions in about 20% of light chains. This indicates that TdT, or an analogous enzyme, must be active in a significant percentage of human B lymphocytes during L chain rearrangement. P Nucleotides are templated bases from the noncoding strand in the coding joint as a result of the formation of hairpin structures generated during recombination. These usually consist of single bases or dinucleotides (Figure 5).

Not all of the proteins involved in this highly regulated DNA recombination event have been identified. Two proteins, RAG-1 and RAG-2, the products of the recombination activating genes RAG1 and RAG2, have signal-cutting activity. They are re-

quired for initiating V(D)J recombination. Studies indicate that there is synchronous cleavage at the two RSSs between the signal and the coding border. Cleavage is a two-step reaction: first, a single-strand nick is made at the 5' end of the heptamer, and secondly, a covalently closed hairpin coding end and a blunt 5' phosphorylated signal end are formed (Figure 5). Mutational analysis indicates that the recombination machinery must interact with both RSSs for cleavage to occur at either signal. Ku, a nuclear DNA repair protein, is also required for V(D)J recombination. Ku is a heterodimer composed of a 70 kDa and an 86 kDa subunit. Both subunits are required to form functional Ku. Ku binds DNA ends in a sequence-independent manner. The Ku heterodimer also associates with a DNA-dependent protein kinase catalytic subunit (DNA-PKcs) to form a trimeric protein called DNA protein kinase (DNA-PK). DNA-PK has serine/threonine kinase activity and requires DNA for activation. One model suggests that following the cleavages by RAG-1 and RAG-2, Ku is then loaded on to the coding hairpin

Figure 6 Joining mechanisms. (A) When two RSSs face in opposite directions the intervening sequences are deleted as circular DNA (deletional joining). (B) When two RSSs face the same direction recombination results in the inversion of intervening sequences without deletion of DNA (inversional joining). (Reproduced with permission from Okada A and Alt FW (1995) The variable region gene assembly mechanism. In: Honjo T

ends and acts to stimulate the joining of the DNA breaks. Signal joints require only Ku and not DNA-PKcs.

Somatic mutation

Somatic hypermutation is a key mechanism in generating antibody diversity. The details of the mechanisms and regulation of somatic hypermutation are unknown. In the human, somatic hypermutation occurs in the presence of antigen, unlike in sheep where antigen-independent somatic hypermutation occurs. The germinal centers of peripheral lymphoid tissues are the sites where somatic hypermutation, positive selection and differentiation of B cells with high-affinity receptors occur. Germinal centers are the only places in the body where antigen is retained for months or years in an extracellular location. Antigen is trapped on the surface of follicular dendritic cells which hold it as an antigen-antibody complex in proximity to nearby B lymphocytes. It is in the microenvironment of the germinal center in which the repertoire of the antigen-specific B cell, influenced by signals from T cells, is shaped. Hypermutation is restricted to V regions and their flanking sequences of H and L chains (Figure 7). Since IgM antibodies undergo somatic mutation, H chain class switching is not required for somatic mutation to occur. Most antibodies expressed as germline sequences are of relatively low affinity. After con-

tacting antigen, mechanisms which generate somatic mutations produce antibodies of higher affinity. There is enrichment of B cells with mutations which confer higher affinity for antigen, while B cells which have acquired stop codons or have lowered affinity are removed by apoptosis. Only rearranged, transcriptionally active Ig genes are mutated, at a rate of

Figure 7 Localization of mutations in the light chain locus. The 5' boundary of mutations is within the leader intron, approximately 150 bp after the transcription promoter (PRO), to approximately 1.5 kb downstream but does not extend into the constant (C) region. (Reproduced with permission from Storb U (1996) The molecular basis of somatic hypermutation of immunoglobulin genes. *Current Opinion in Immunology* 8: 206-214.)

approximately 10^3 per bp per generation. Both productive and nonproductive rearrangements are substrates for mutation. There are several features characteristic of the hypermutation process: 1) mutations are mainly point mutations, with very rare deletions or insertions of mostly single nucleotides, 2) there is one strand of the double helix which is preferentially targeted, 3) foreign DNA in the context of an immunoglobulin transgene is somatically mutated, suggesting that the targeted sequence itself does not initiate the mutation process, 4) hotspots of mutation are observed at different positions in different sequences suggesting that the process is influenced by the primary DNA sequence, 5) the 5' boundary of mutations is within the leader intron, and 6) while there is no defined 3' end-point of the mutation tract, mutation does not extend into the C region. A current model indicates that transcription is necessary for mutation to occur.

Heavy and light chain association

In theory, there is random combination between any H and L chain. The combinatorial pairing of H and L chains does serve to increase the antibody repertoire, but not to the extent contributed by VDJ joining and coding joint manipulation. Antibodies with different specificities are found to have identical V_L domains paired with different V_H domains. Using recombinant antibodies, L chains were demonstrated to modulate or inhibit binding of antigen.

Studies indicate that B cells which produce antibodies having self-reactivity with high-affinity for their antigen can resynthesize a different L chain. This process, referred to as receptor editing, indicates that cells which produce autoantibodies can exchange L chains, and following successive pairing with the H chain, produce a final Ig product which does not have high-affinity recognition for self antigens. It is suggested that this is an antigen-directed mechanism used by immature autoreactive B cells to change the specificity of the receptor in order to escape tolerance. Defects in this editing process may lead to the accumulation of high-affinity, self-reactive antibodies.

DNA vaccines represent a novel vaccine approach which employs genes encoding proteins of pathogens or tumors, rather than the proteins or pathogens themselves as in more conventional approaches. The vaccines consist of bacterial plasmids containing a strong viral promoter which will function in mammalian cells, a gene encoding the protein antigen, and a polyadenylation sequence and transcriptional terminator, all placed in a vector backbone that permits replication of the plasmid (for purposes of production) in a bacterial host. Thus the plasmid is produced through standard recombinant technology by bacterial fermentation, yet the plasmid does not replicate following injection into a vertebrate. Rather, there, the protein antigen is produced *in situ* and can elicit immune responses. From an immunological standpoint, the advantage of this technology is that both humoral and cellular immune responses are generated, with the production of antibodies, and both helper and cytolytic T cell responses.

Although the initial demonstration of the protective efficacy of such a vaccine in an animal challenge model was published only in 1993, promising pre-clinical results have been observed in a number of disease models representing various classes of disease targets (viral, bacterial and parasitic infections as well as cancer) and various animal species including nonhuman primates. The ultimate value of the technology awaits the results of clinical trials which are at very early stages. Nevertheless, this technology makes it possible to study some fundamental issues of antigen processing and presentation and to evaluate the potential role of various antigens and types of immune responses for protection against certain diseases, as well as offering potential solutions to some of the challenges of vaccine development. The latter include: generation of cytotoxic T lymphocyte responses which can recognize epitopes from conserved proteins on infected cells and thus may provide broader protection against different strains of a virus; presentation to elicit antibodies to antigen that has post-translational modifications, conformation and oligomerization which may be more appropriate for protein antigens that normally are made by the vertebrate host cell; potentially long-lasting immune responses (perhaps due to long-term expression of antigen); and a ready ability to combine diverse

immunogens into a single preparation to decrease the number of vaccinations required.

This entry will focus on the immune responses generated by DNA vaccines and describe the mechanisms whereby the vaccines induce the immune response. For a review of the disease models in which clinical efficacy has been shown and immunogenicity demonstrated the reader is referred to Donnelly, Ulmer, Shiver and Liu, 1997.

DNA vaccine technology grew from an observation that *in vivo* injection of plasmid DNA encoding reporter genes resulted in the *in situ* production of protein, with muscle being the site that resulted in the greatest expression of protein. The DNA was simply injected as a saline solution without any requirement for special delivery agents such as the cationic lipids that are used for DNA transfection *in vitro*. An alternate means of delivery, and the ability of the expressed protein to induce antibody responses, were subsequently described using a biolistics delivery device known as a 'gene gun' which propelled DNA precipitated onto gold beads into the skin.

The initial demonstration that *in vivo* injection of DNA encoding an antigen could result in immune responses that were protective against viral challenge, and moreover in major histocompatibility complex (MHC) class I-restricted T cell responses (which were protective against cross-strain challenge), utilized plasmid DNA encoding an internal protein of influenza A virus injected intramuscularly in mice in saline. The generation of class I-restricted cytotoxic T lymphocytes (CTLs) was of particular interest, because such responses are thought to require the endogenous production of the protein antigen, so that the protein can enter the proteasome/TAP transporter processing pathway and the resulting epitope peptides can associate with MHC class I molecules in the endoplasmic reticulum. Because most exogenous proteins preferentially enter the MHC class II/endosomal pathway rather than this class I antigen-processing pathway, vaccines that are not live intracellularly growing organisms do not generally result in the induction of MHC class I-restricted CTLs. DNA vaccines thus provided a means of generating these CTLs without the use of a live replicating vector. The ability to generate CTLs

by providing intact proteins (rather than peptides), allows determinant selection to occur, thus broadening the potential applicability to a diverse population. The mechanisms whereby this occurs will be addressed below.

The ability of a DNA vector encoding an internal conserved protein, nucleoprotein (NP), to generate CTLs as well as cross-strain protection provides an example of the responses that have been observed in various other systems. Immunization with DNA encoding the NP of the 1934 H1N1 strain A/PR/8/34 protected mice from subsequent lethal challenge with the heterosubtypic 1968 H3N2 strain A/HK/68 (Figure 1). CTLs that recognized the MHC class I (H2K^d)-restricted epitope of NP were generated and were capable of lysing both peptide-pulsed and virally infected target cells. This was true for spleen cells specifically restimulated with antigen, as well as for spleen cells activated without antigen using only cytokine. Immunization with recombinant NP prepared in a baculovirus expression system did not produce MHC class I-restricted CTLs or cross-strain protection under these conditions. Transfer of restimulated splenocytes but not sera from immunized animals conferred the same cross-strain protection on recipient mice. Thus immunization with DNA encoding a conserved protein was shown to be capable of generating CTL responses which, as shown in this model, were effective at mediating protection against a different strain of virus, against which strain-specific antibodies would be ineffective.

More recently immunization with NPmut, a plasmid encoding a full-length mutant form of the same NP in which the anchor residues of the H2K^d-restricted 147–155 epitope were altered to prevent its binding to H2K^d, was observed to induce CTL directed against a recessive class I-restricted epitope. These CTLs were likewise protective against cross-strain challenge. Thus the DNA vaccine preserved the hier-

archical order of immunogenicity of the epitope peptides for the induction of the CTLs.

Since immunization with DNA encoding proteins results in protein synthesis in the definitive host, one would predict that such a protein would be similar or identical to the wild-type protein produced by viral infection. This is in contrast to chemically inactivated virus, in which surface proteins may be cross-linked, or recombinant proteins which may have different post-translational modifications, conformations or ability to oligomerize. While this appears to be an advantage for viral and tumor antigens, it may be an issue for bacterial and parasitic proteins as discussed below for *Mycobacterium tuberculosis*.

An example of the potential advantage of a DNA vaccine for generating native antigens for B cell responses is the hemagglutinin (HA) of influenza virus, which is the major surface glycoprotein of influenza against which virus-neutralizing antibodies are directed. Current influenza vaccines are grown in eggs, which may select for variants with HA sequences differing from the sequences of virus grown in mammalian cells, and are inactivated with formalin. These vaccines provide significant but highly strain-specific immunity. DNA vaccines could encode the exact sequence of mammalian isolates and avoid any chemical alterations, while providing the conformational epitopes needed for inducing protective antibodies. In fact, doses as low as 1 µg of DNA (given twice) provided complete protection against homologous challenge. The antibodies were similar to those induced by natural infection in the predominance of the IgG2a subtype. In contrast, immunization with inactivated virus yielded equivalent titers of IgG1 and IgG2a. Studies in primates have shown that DNA vaccines elicit HI antibody titers equal to or greater than those induced with inactivated whole or split virus.

Splenocytes from DNA vaccine-immunized ani-

Figure 1 Cross-strain protective immune responses to influenza in mice immunized intramuscularly with NP DNA. Groups of 10 female BALB/c mice were injected at 4, 7 and 10 weeks of age with 100 µg of plasmid DNA encoding the NP from influenza A/PR/8/34 (H1N1) (solid squares), or with control vector (open squares). Intramuscular injections were given in both quadriceps muscles in a total volume of 100 µl. Mice were challenged with 200 TCID₅₀ of influenza A/HK/68 (H3N2) at 13 weeks of age. (Reproduced with permission from Montgomery D et al (1993) *DNA and Cell Biology* 12: 777–784.)

mals proliferated when re-exposed to antigen *in vitro*. In addition secretion of interleukin-2 (IL-2) and interferon γ (IFN γ) but not IL-4, were seen, consistent with a T_H1-like response. The predominance of IgG2a responses in mice following immunization with various DNA vaccines gives further evidence of the generation of T_H1-type helper responses.

These specific and protective immune responses have been seen in various other disease models. In a cottontail rabbit papillomavirus (CRPV) model, we have shown that immunization with DNA encoding the major capsid protein, L1, protected against wart formation following challenge with CRPV. In viral infection, L1 is directed to the cell's nucleus for assembly into capsids which are recognized by neutralizing antibodies. Hence, it was not clear that DNA immunization would yield the antigen in an accessible and appropriate conformational form. Yet, vaccination of rabbits with L1 DNA generated neutralizing antibodies which protected rabbits from development of warts upon challenge and which persisted undiminished in titer for 32 weeks or more. Transfer of immune serum prior to infection likewise protected the animals.

The ability of a vaccine to generate immune responses effective for pathogens that initially infect via mucosal surfaces may determine the effectiveness of such a vaccine. Immunization with DNA encoding gD and gB of herpes simplex virus type 2 (HSV-2) induced neutralizing antibodies against these envelope glycoproteins and protected guinea pigs in a mucosal challenge model.

DNA vaccines encoding proteins of *M. tuberculosis* have been shown to be effective for generating the desired cellular responses and protection from challenge. This model has been instructive, in that in this system the mycobacterial protein is made by the mammalian host cell rather than by the organism, and therefore the post-translational modifications of the protein have in some cases been different from those of the native protein. To avoid the glycosylation that was seen of one particular antigen, antigen 85C, selected point mutations were introduced to remove the N-linked glycosylation sites and thus to generate an antigen more like the native protein in its lack of glycosylation.

Although both intramuscular (i.m.) and intradermal (i.d.) immunization result in antibodies, i.m. immunization has been the only route resulting in significant cross-strain protection (for influenza) and has been the route yielding the highest levels of helper cell responses (for HIV env). Potential mechanisms for antigen presentation after i.m. DNA immunization include:

1. synthesis and presentation of antigen by the myocytes,
2. synthesis of antigen by the myocytes followed by uptake of some form of the protein by an antigen-presenting cell (such as a bone marrow-derived dendritic cell), or
3. the presence of DNA (either by direct uptake or transfer from myocytes) in antigen-presenting cells in addition to the myocytes.

Studies utilizing parental $\rightarrow$ F1 bone marrow chimeric mice have demonstrated that following i.m. immunization with NP DNA, all of the CTLs that were detected were restricted by the MHC class I haplotype of the bone marrow donor. Thus, only professional antigen-presenting cells (APCs) were able to prime the CTLs for an MHC class I-restricted response. Therefore, muscle cells may synthesize antigen, but do not present antigen for priming of CTLs after DNA immunization i.m. Conversely, it is not necessary to invoke direct transfection of APCs by the DNA since if myoblasts that are permanently transfected to express NP were transplanted into similar bone marrow chimeras, the CTLs were again restricted to the donor haplotype even if the myoblasts were of the other parental haplotype. Thus production of an antigen by myocytes is sufficient for the induction of CTLs, indicating that transfer of some form of antigen must occur, possibly the 'cross-priming' reported in other systems.

The plasmid DNA appears to also have adjuvant activity which may influence both the magnitude and the type of immune responses. For example, although immunization with recombinant NP resulted in the generation of comparable levels of IgG1 and IgG2a in mice, addition of noncoding plasmid DNA to the recombinant NP shifted the isotype of the antibodies to a predominance of IgG2a, as is seen in the case of immunization with NP DNA or following infection with live influenza virus. Addition of noncoding plasmid DNA to DNA coding for influenza HA also increased the titer of HA-specific antibody in nonhuman primates. The mechanism for this adjuvant effect of DNA is unclear. Certain motifs of the DNA base pairs (sequences containing CpG) that are more common in bacterial DNA may play a role since oligomers containing these motifs have been shown by various groups to be mitogenic for lymphocytes *in vitro*. Very preliminary data *in vivo* have yielded more complex results as to whether or not the presence of such motifs in the plasmid play any role in increasing immune responses to the protein encoded by the DNA.

A number of potential issues related to safety need to be more fully explored as the clinical utility of

DNA vaccines is being determined. Questions which must be answered include: does integration of the plasmid occur that may potentially lead to insertional mutagenesis? Does induction of pathogenic anti-DNA antibodies occur? Does immunologic tolerance develop if the production of antigen persists? Studies to date have failed to demonstrate integration, induction of pathogenic anti-DNA antibodies, or tolerance. Indeed, regarding the latter point, DNA vaccines have been seen to prime and boost well.

While the work presented here has focused upon viral and bacterial diseases, the same attributes may provide a useful prophylactic or immunotherapeutic approach to parasitic diseases or cancer.

In summary, DNA vaccines may provide a broadly applicable technology for generating protective cellular and antibody responses. Although a number of issues still need further exploration (e.g. safety, mechanisms of immunogenicity), DNA vaccines have given promising results in a number of preclinical studies and have provided a tool for studying mechanisms of antigen presentation and for antigen discovery for vaccines.

DOMAINS, IMMUNOGLOBULIN-TYPE

The notion that immunoglobulin (Ig) chains are made up of homologous modular units arose in the mid-1960s, when the pioneering experiments of Porter, Nisonoff and Milstein had already revealed the periodic distribution of disulfide bridges along the polypeptide chains, and several groups were reporting the first partial amino acid sequences that confirmed the internal similarities in light and heavy chains. Taken together, these results suggested that Ig chains arose by successive duplications of a common ancestor gene. A repeated segment of about 110 amino acids, the Ig homology unit, was thus identified.

At the same time, a structural model of the antibody molecule was emerging from a wealth of biochemical and biophysical evidence. Tanford and coworkers proposed, in 1965, the now classic Y-shaped model of the IgG molecule consisting of three globular compact structures, the Fc and two Fab fragments. Ultrastructural support for this model was soon provided by Valentine and Green's electron micrographs of rabbit IgGs. Furthermore, the apparent size of the molecule was consistent with the first preliminary X-ray studies of immunoglobulin crystals, and small-angle X-ray scattering studies were compatible with a flexible Y-shaped model for the IgG molecule.

In this context the notion of homology unit evolved into the domain hypothesis. In 1969 Edelman and coworkers reported the first complete sequence of an Ig molecule and suggested that each repeated homology unit folds into a compact structure, the Ig-type domain. This hypothesis not only placed the domain at the evolutionary origin of immunoglobulins, but also recognized that different domains evolved to serve different biological functions. The Ig-type domain was therefore conceived to be a unit of sequence homology, molecular evolution, protein architecture and biological function.

The Ig fold in antibodies

The structural implications of the domain hypothesis were confirmed in 1973 by the first detailed X-ray diffraction studies of immunoglobulin fragments. The three-dimensional structures of a Bence Jones protein and of Fab fragments from myeloma proteins established that the postulated domains are indeed spatially separated and share a common pattern of polypeptide chain folding, the Ig fold. Since then, the

introduction of myeloma hybridization techniques for the production of monoclonal antibodies and the impressive advances in molecular biology and biophysical techniques have greatly stimulated further biochemical and structural studies of immunoglobulin fragments. Detailed three-dimensional structures are now known for a large number of antibody fragments and antigen-antibody complexes, as well as for non-Ig proteins bearing one or more Ig-type domains, thus providing a basis for the understanding of the important role of the Ig-type domain in biological recognition.

Basic structure of the Ig fold

Immunoglobulin domains fold into a globular, compact structure that fits into a parallelepiped of approximately $40 \times 25 \times 25 \text{ \AA}$ ($1 \text{ \AA} = 10^{-10} \text{ m}$). The basic folding motif consists of two layers of anti-parallel β sheets that surround an internal volume closely packed with hydrophobic side-chains. The overall shape of the domain can be described as a flattened cylinder (β barrel) or sandwich-like structure of two β -pleated sheets (Figure 1). The variable (V) and constant (C) subunits of immunoglobulins differ in the number and regularity of the β strands forming the bilayer: the C domains are built up from seven β strands arranged such that four strands form one β sheet and three strands form a second sheet, whereas the V domains contain nine β strands instead of seven. The two additional strands in V domains, inserted at the edge of one β sheet, are functionally important since they define the second hypervariable region directly involved in the formation of the antigen-recognition site.

The topology of a protein domain – that is the order in which the elements of secondary structure are connected to each other in the three-dimensional structure – is a distinctive feature that serves to establish a taxonomy of protein folding patterns. The topology of the Ig fold is quite simple (Figure 1) and is usually represented in the form of a 'Greek key barrel' (so called since the two-dimensional topological diagram is reminiscent of the motifs observed in old Greek pottery). As a result of this topology, there are at least two β strands, consecutive in the sequence but not contiguous in space, that are linked by a connecting loop crossing the top or bottom of the β barrel (the first hypervariable loop of V domains is one example). All Ig-type domains are topologically equivalent, and this unique pattern of linkages may be

Figure 1 Structural diversity of Ig-type domains. The constant domain of antibodies (Ig C_L) represents the common core present in all Ig-like structures, composed of seven antiparallel β strands labeled A–F. The two-dimensional topological diagram (bottom, left) shows the connected Greek key motif of this structure. Also shown are selected examples of Ig-type domains from different subtypes: Ig V_L, variable domain of an antibody light chain; TCR-V _{β} , variable domain from a T cell receptor β chain; CelD, N-terminal domain of a bacterial cellulase; FN-III, fibronectin type III domain of tenascin, an extracellular matrix glycoprotein expressed during embryonic development; Tik, C-terminal domain of smooth muscle myosin light chain kinase; B₂mg, β_2 -microglobulin

considered as the ‘signature’ of the immunoglobulin fold.

The loops connecting the β strands are relatively short and, as a result, a majority of the residues of the domain are contained in the two β sheets. The strands exposed to solvent display the characteristic pattern of alternating polar–apolar residues, with the apolar side-chains extending towards the interior of the domain to form a hydrophobic core between the two β sheets. Most of the conserved residues in V and C domains of antibodies are found in this internal core, in particular two highly conserved cysteine residues which form an intramolecular disulfide bridge linking the two β sheets. Other core positions show extensive amino acid substitutions, but preserve the secondary and tertiary structures and, to a lesser extent, the hydrophobic character of the protein interior. At the two extremities of the domain structure, the β strands are connected by peptide loops of varying length and character. These connecting segments may form regular reverse turns or short α -helical stretches, but in most cases present an irregular structure.

Domain association

The Ig domains of antibodies are associated in pairs stabilized by noncovalent interactions. With the exception of the C_{H2} domains, Ig subunits interact over a large contact area and are tightly associated.

The variable domains associate to form V_H–V_L heterodimers in Fab fragments, or V_L–V_L homodimers in Bence Jones proteins, by face-to-face packing of the five-stranded β sheets. Two V domains are related by an approximate (heterodimer) or exact (homodimer) twofold axis of symmetry. Inter-subunit interactions are very extensive, with roughly 20% of the entire molecular surface of each domain buried upon dimerization. Highly conserved amino acid residues at the V_H–V_L interface allow the association of different pairs of light and heavy chains to form the antibody molecule.

The constant domains of antibodies and Bence Jones proteins also form closely packed dimers. As in V dimers, paired C domains are related by an approximate (C_{H1}–C_L) or exact (C_L–C_L, C_{H1}3–C_{H3}) twofold axis of symmetry, and the arrangement of subunits among all the C-type pairs studied is very similar. There is, however, a reversal of domain–domain interactions compared to V dimers: C dimers are formed by a close packing of the four-stranded β sheets which in V domains are exposed to solvent.

The antigen-recognition site of the antibody molecule involves the hypervariable loops which connect the β strands at the distal extremity of the V_H–V_L dimer. Functional differentiation of variable domains is accomplished through extensive genetic restructuring of this region (amino acid insertions, deletions and substitutions), which confers the antibody mol-

ecule with a potentially unlimited range of antigen binding specificities without significantly affecting the basic structural framework of the Ig domains.

The Ig-type domain in non-Ig molecules

First described in Ig molecules, the characteristic β -sheet fold of the Ig-type domain has also been found in a large number of proteins of diverse biological function. Many of these proteins share additional genetic and functional similarities with Ig domains, which suggests a common evolutionary origin, and are thus grouped together into the so-called Ig superfamily. The presence of one or more Ig-type domains in members of the Ig superfamily can be inferred by sequence homology, and has been demonstrated in various cases by crystallographic analysis (for example, Ig H and L chains, T cell receptor (TCR) α and β chains, major histocompatibility complex (MHC) class I and class II, surface antigens CD2, CD4, CD8, β_2 -microglobulin, neuroglian, tenascin). However, structural studies have also revealed the presence of Ig-like domains in proteins which bear no sequence homology with the Ig superfamily. Examples include proteins as diverse as chaperones (the protein PapD required for the assembly of pili in bacteria), enzymes (a bacterial cellulase and a fungal galactose oxidase), and viral proteins (the major envelope protein from a flavivirus), for which the presence of one or more Ig-type domains was unexpected prior to structure determination.

The structure of the Ig-type domain present similar

features in all these proteins, independently of any genetic or functional relationships. The Ig-type domains consist of a β barrel composed of seven to nine antiparallel β strands with the typical Greek key topology, and display a structurally conserved core that includes the central strands from the two β sheets. Also, the hydrophobic character of the internal space between the β sheets (mostly composed of aliphatic and aromatic side-chain residues) is maintained. In contrast, the length and regularity of the β strands as well as the length and structure of the connecting loops are extremely variable (Figure 1). Indeed, the Ig-domain topology can be achieved by quite different sequences and, as a result, no single interaction or amino acid position can be uniquely identified as the principal determinant of the structure. For example, the intramolecular disulfide bridge linking the two β sheets in antibody domains, early recognized as a hallmark of the Ig fold, is not necessary to determine the Ig-type domain structure. Even within the Ig superfamily, these cysteine residues can be found at different positions in the β sheets or may be completely absent.

As initially observed in antibodies, the Ig-type domains in other proteins often associate in pairs to form homo- or heterodimers. Noncovalent association of Ig-type domains usually occurs through the exposed faces of the β sheets, giving rise to compact globular dimers as shown in Figure 2 for the surface antigen CD8 and the Fab fragment from an Ig molecule. On the other hand, head-to-tail interactions predominate between consecutive Ig-type domains

Figure 2 Different types of subunit association between Ig-type domains. The human growth hormone receptor is shown with its bound ligand. Only the two N-terminal domains of CD4 are shown. Neuroglian is a modular protein involved in neural cell-cell adhesion. The extracellular portion of neuroglian consists of 11 Ig-like domains, two of which are shown here.

along a single polypeptide chain (e.g. the CD4 co-receptor of T lymphocytes and neuroglian, a protein involved in cell–cell adhesion, shown in Figure 2). In these membrane-bound extracellular proteins containing several Ig-type repeats, head-to-tail interactions give rise to elongated quaternary structures that may serve, for example, as structural ‘spacers’ allowing the molecule to interact with a distant target such as another protein on a neighboring cell.

Ig-type domains occur in functionally diverse proteins that interact with a wide range of ligands, from metal ions to very large proteins. The available crystal structures reveal that every region of the domain surface can be used for interaction with other molecules. For example, the loop regions determine the ligand (antigen)-binding site in antibody V domains, whereas many other Ig-type domains interact via part of their β sheets. This functional differentiation of Ig-type domains is even possible within a single protein. In fibronectin, for example, the interaction with ligand may be mediated by a single loop (the RGD motif) or by other parts of the molecular surface, and possible ligands include carbohydrates, other Ig-like domains, or even a whole network of molecules. Quite often, the ligand-binding site is defined by a cleft between two consecutive Ig-type domains, as in neuroglian (Figure 2) where domain dimerization creates a metal ion-binding site. The chaperone PapD and the extracellular regions of the receptors for growth hormone (Figure 2) and interferon γ also use two consecutive Ig-type domains to bind their respective protein ligands.

Whether the result of the evolutionary divergence from a common ancestor gene or the convergence towards a particularly stable structure, the Ig-type domain represents a rich source of natural variation on a single structural theme, and additional studies

will undoubtedly reveal further unexpected features about its ubiquitous nature and functional diversity.

DRUGS, ALLERGY TO

Timothy J Sullivan, Department of Medicine, Emory University School of Medicine, Atlanta, Georgia, USA

Pharmacologically active agents administered to humans for diagnostic or therapeutic purposes can cause a wide range of immunologically mediated diseases. Drugs can act as immunogens that induce immune responses and then elicit immunopathologic reactions. In addition, a variety of agents used in human medicine can activate immune effector systems through pharmacologic rather than immunologic mechanisms. Opiates can cause mast cell

mediator release by activating cell surface opiate receptors. Aggregated immunoglobulin G (IgG) in heteroantisera can activate complement and thereby produce anaphylaxis. Some drugs can induce autoimmune syndromes in which the specific immune responses are directed toward self rather than drug-related determinants.

Allergic (immunologically mediated) reactions to drugs cause increased morbidity, and rarely fatal out-

comes, in individuals already sufficiently ill to warrant pharmacologic intervention. About 1–5% of hospitalized patients experience an allergic reaction to a medication. Approximately 10% of adults have experienced an allergic reaction to a drug. Identification of the offending agent, reversal of the immunopathologic processes, and introduction of effective alternative therapy can be very difficult challenges. The human and financial costs of these reactions are considerable. In fact, the morbidity and mortality induced by allergic reactions to drugs unambiguously make this one of the most important categories of immunologically mediated disease.

Inherent in drug therapy of humans is the administration of potential immunogens in standard doses and intervals in the context of somewhat similar clinical disorders. As relevant drug epitopes are defined in biochemical terms, primary and secondary immune responses can be studied in the context of current understanding of immunogenetics, immunoregulation and immunopathology. Studies of specific immunoglobulin and lymphocyte responses to drugs in relation to clinical drug allergic reactions have provided fundamental insights into IgE-mediated anaphylaxis, immune cytopenias and solid tissue inflammation. Drug therapy of humans permits both the systematic testing of hypotheses generated from basic immunologic knowledge and the generation of diverse new hypotheses to be assessed in model systems.

Drugs as antigens

The administration of insulin, heteroantisera and other macromolecules to humans frequently causes immune responses. For example, many diabetics treated with insulin, even recombinant human insulin, produce IgG to insulin. In most instances, the immune response to the complete antigens used in human medicine does not lead to clinically detectable immunopathologic reactions or to significant neutralization of function. Low molecular weight drugs, in contrast, usually are not capable of causing immune responses or eliciting immunopathologic reactions in their native states. Covalent linkage of a drug, or a reactive metabolite of a drug, to a macromolecule creates an epitope that can cause immunologic reactions. Landsteiner designated the covalent binding process 'haptentation' and the drug-derived epitope a 'hapten'.

Two principal forms of haptentation have been documented (Figures 1 and 2). β -Lactam antibiotics such as penicillin and a small number of other drugs used in clinical medicine are intrinsically reactive with proteins and, therefore, are capable of direct

Figure 1 Haptentation of cells and extracellular molecules by intrinsically reactive compounds. β -Lactam antibiotics and other reactive agents rapidly form covalent bonds with cell surfaces, extracellular matrix, soluble proteins, amino acids and other molecules. A dynamic array of sparsely to densely substituted solid phases and a fluid phase with univalent and multivalent substituted carriers is formed.

Figure 2 Haptentation of cells and extracellular molecules by molecules with little or no intrinsic reactivity. Metabolism of drugs (occurring primarily within hepatocytes, keratinocytes and other cells) can create reactive intermediates that can form covalent linkages to carrier molecules. Haptentation of molecules being synthesized in the cell at the time of drug metabolism can result in long-lasting surface expression of haptentated molecules and secretion of univalent and multivalent carriers. Reactive metabolites also may escape to the extracellular space to haptentate any suitable carrier.

haptentation (Figure 1). Cell surfaces, extracellular structural proteins and diverse soluble molecules become haptentated. Approximately 10% of the penicillin molecules administered become covalently bound to human cells, proteins and other body constituents. Individual cells can accumulate thousands of surface haptent determinants within minutes of

exposure to therapeutic concentrations of β -lactam antibiotics.

Most low molecular weight substances used in clinical medicine are not reactive with macromolecules. As depicted in **Figure 2**, however, metabolites of some medications can haptenate. Intracellular haptenation of proteins being synthesized at the time of drug exposure can lead to haptenation of molecules eventually expressed on the cell surface, or to release of haptenated cellular secretion products. Extracellular metabolism or release of reactive intermediates into the extracellular space also can lead to cell surface haptenation and haptenation of fixed and soluble extracellular molecules.

Thus, the generation of immunogenic haptens and of targets for immunopathologic reactions occurs by diverse pathways. A dynamic array of haptenated cell surfaces, haptenated fixed proteins such as collagen, soluble molecules bearing single hapten substituents (univalent carriers), and soluble molecules bearing multiple hapten substituents (multivalent carriers) appears during drug therapy.

Factors influencing reactions to drugs

Clearly the structures, metabolism and chemical properties of specific drugs and their metabolites have important influences on human immune responses and the expression of clinical allergic reactions. The dose, route, duration and frequency of therapy also can influence the expression of allergic reactions to drugs. In addition, active disease processes, such as infections, and a variety of individual patient factors influence responses.

The presentation of drug antigens during an infection can be influenced by products released from the infectious agent. Bacterial endotoxins markedly alter the local and systemic immunoregulatory environment. Lysis of bacteria just after the administration of microbicidal drugs abruptly increases the amount of free endotoxins and causes striking increases in the levels of tumor necrosis factor (TNF), interleukin 1 (IL-1) and other cytokines. Certain microbes release superantigens, supercarriers (proteins that when haptenated elicit very strong antihapten responses), and immunomodulatory proteins that can affect immune responses to drugs.

Several human factors also can influence the expression of drug allergy. While the full importance of HLA class I and class II genes in drug allergy is not clear, both class I and II associations have been detected for some allergic reactions to some drugs. Genetically determined differences in drug metabolism are known to influence susceptibility to reactions to some drugs, including isoniazid and hydrala-

zine. A familial propensity to allergic reactions to structurally diverse antimicrobial drugs has been reported.

Some individuals have a propensity to react to haptenating drugs. If a patient has had an allergic reaction to one antimicrobial drug, there is an approximately ninefold increased risk of reacting to another class of antimicrobial drug. Approximately 10% of adults have reacted to one class of antimicrobial drug and are in this high-risk category. The classes of agents causing these reactions are structurally diverse and the spectrum of immunopathologic reactions expressed is broad. The principal abnormality in these patients appears to be a consistent expression of an immunoregulatory environment during infections that favors immune responses to haptens presented during an infection. Overall, approximately one-half of allergic reactions to antimicrobial drugs occur in individuals who have reacted to different classes of antimicrobial drugs in the past.

Clinical reactions to drugs

Immune responses to drugs are necessary but not sufficient for clinical allergic reactions to drugs. If the fluid phase has an excess of univalent haptenated carriers over multivalent carriers, many immunopathologic reactions will not occur. Cross-linking of IgE and activation of mast cells will not occur. Immune complexes cannot form in univalent hapten excess. Direct cytotoxic reactions are inhibited by fluid phase determinants. The affinity and isotype arrays of the immunoglobulins expressed also influence the nature of a reaction.

Counter-regulatory responses and nonimmunologic factors exert important influences on clinical expression of immunopathologic reactions. Individuals vary considerably in mast cell releasability, cellular resistance to cytotoxic attack, handling of immune complexes and susceptibility to other forms of immune injury. Superimposed on these immunologic considerations are the toxic and pharmacologic effects of some drugs that can mimic or add to specific immune reactions.

Stratification of clinical allergic reactions to drugs according to the immunopathologic scheme of Gell and Coombs can be considered. Type I IgE-mediated immediate hypersensitivity reactions do occur in the forms of anaphylaxis, urticaria and angioedema, but some drugs can induce these reactions via complement activation or direct pharmacologic effects. Type II cytotoxic reactions occur, for example immune cytopenias, but most cell-destructive or tissue-inflammatory reactions to drugs are difficult to

distinguish from type III and in some cases type IV reactions. Adding to the complexity of using a pathophysiologic stratification scheme is the frequent concurrence of multiple immunopathologic mechanisms. Sulfonamides, cefaclor and other commonly used drugs can induce reactions that include urticaria, fever, joint inflammation and variable vascular and solid tissue disorders that defy this form of stratification.

While a pathophysiologic stratification is routinely attempted, clinical stratification is more widely used to guide diagnosis, therapy and prognosis (Table 1). This classification scheme permits discussion, investigation, diagnosis and rational management of reactions of probable but unknown immune mechanisms such as drug fever and the Stevens–Johnson syndrome.

As summarized in Table 1, the clinical manifestations of drug allergy are quite diverse. The known variations in sites and intensity of haptentation, in patterns of immune responses and in tissue responses to these forces make these diverse clinical phenomena expected.

Diagnosis of drug allergy

Allergic reactions to drugs must be distinguished from similar clinical phenomena of different causes. Two forms of immunologic diagnosis then must be made: identification of the specific cause of the reaction, and identification of the immunopathologic

mechanisms mediating the reactions. All possible causal agents are identified and then stratified according to known propensities to cause the specific pattern of clinical disease; the temporal relationships of drug exposures to the onset of the reaction; the effects of drug discontinuation; and the effects of rechallenge (if this has occurred).

A rapidly expanding array of immunodiagnostic tests has been developed for the detection of specific responses to antimicrobial drugs and selected other classes of drugs. These include tests for IgE (by immediate wheal and flare skin tests, radioallergo-sorbent-RAST tests and leukocyte histamine release tests), IgG, IgM and IgA (primarily by ELISA), and specific lymphocytes (lymphocyte transformation tests). The presence of IgE to a drug that was given shortly before the onset of anaphylaxis, urticaria or angioedema provides strong evidence of a causal role. The presence of IgG, IgM, IgA or specific lymphocyte responses are much less closely related to clinical allergic disease – these responses are detectable in many individuals who do not have overt immunopathologic reactions to the drug. Nevertheless, evidence of an immune response to a drug given in appropriate temporal relationship to a reaction supports a possible causal role. The combination of clinical and immunologic assessments usually can identify the cause of a reaction, permitting continued use of other classes of needed medications.

Recent basic research has permitted clinical assessment of some immune effector systems, greatly facilitating pathophysiologic diagnosis and monitoring. Assays for serum mast cell tryptase permit biochemical diagnosis of anaphylaxis, a major improvement over assays for histamine and prostaglandin D₂ or their metabolites which arise from several cellular sources in addition to mast cells. Assays for complement anaphylatoxins C3a, C4a and C5a as well as other complement activation markers permit assessment of classical and alternative pathway complement activation during allergic drug relations. Emerging biochemical, histochemical, and molecular biological assays for mediators, cytokines and immunologically relevant cell activation should allow progressively more precise identification of active effector systems and the impact of pharmacologic or immunologic interventions.

Management of drug allergy

Acute allergic reactions to drugs usually are treated by withdrawal of the offending drug and conventional pharmacologic interventions appropriate for the specific reaction pattern (Table 1). In some instances, when no effective alternative therapy is

Nephritis

available and when the reaction is restricted to a pruritic rash, the drug can be cautiously continued with pharmacologic suppression of the reaction.

Several procedures have been developed to avoid or minimize reactions in high-risk populations. Among antibiotic allergic patients, vigorous efforts are made to correct factors predisposing to infections; to document infection before therapy; to avoid classes of drugs associated with prior reactions; to screen with immunodiagnostic tests; and to administer the first dose in a course of therapy under medical supervision. When possible, initial doses are given orally.

Premedication with H_1 antihistamines and systemic glucocorticoids, coupled with the use of nearly isosmolar radiocontrast media (RCM), minimizes RCM reactions in high-risk patients. Similar pharmacologic premedication is used to suppress other pseudoallergic reactions such as reactions to aggregated immunoglobulin.

Patients with IgE sensitivity to drugs that are required for therapy (e.g. insulin, penicillin in some cases) can be desensitized over a period of hours. Initial doses, usually selected on the basis of skin test reactivity, typically are 1/10 000 of a conventional dose. Increasing doses are administered at 15–20 min intervals until a therapeutic dose is reached. Conventional therapy can then be used, with no lapses in therapy.

As assessed by wheal and flare skin test responses, antigen-specific mast cell desensitization occurs during this procedure. Mast cell reactivity and clinical sensitivity return within 1–3 days after discontinuation of the drug in most patients. The most widely held hypothesis is that the gradual introduction of antigen favors univalent haptentation, resulting in hapten inhibition and gradual cross-linking of mast cell surface IgE, resulting in avoidance of clinically significant mast cell mediator release.

E

ECHINOCOCCUS, INFECTION AND IMMUNITY

David J Jenkins, The Australian Hydatid Control and Epidemiology Program, Canberra, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The tapeworm parasites of the genus *Echinococcus* (Class Cestoda) are divided into four species. Two are restricted to central and south America (*E. oligarthus* and *E. vogeli*) and very little is known about their immunobiology. The other two species (*E. granulosus* and *E. multilocularis*) are important zoonoses and have been studied extensively. *E. granulosus* occurs worldwide and its distribution has been greatly assisted at various times in history through the translocation of domestic animals during periods of human colonization. *E. multilocularis* is found mainly in holarctic regions, but it also occurs further south in some regions of Europe and North America. The cycle of transmission of *Echinococcus* involves the interaction between carnivores (definitive hosts) and herbivores/omnivores (intermediate hosts), with each host type containing one of two morphologically distinct parasite stages.

Definitive hosts are usually domestic and wild canids, but in some parts of the world these may be domestic or wild felids. Definitive hosts are infected with the tapeworm stage of *Echinococcus*. These tapeworms reside in the small intestine, are small and may be present in huge numbers. Infections of over 100 000 worms are not uncommon in Australian wild dogs (dingoes and dingo/domestic dog hybrids).

Ungulates (sheep, cattle, pigs, deer, camels) are the most common intermediate host but rodents, macropod marsupials or humans may also become infected. Intermediate hosts are infected through accidental ingestion of eggs passed into the environment with the feces of infected definitive hosts. Following ingestion and hatching of the eggs, oncospheres are released into the intestine. The oncospheres move through the intestinal mucosa and enter the hepatic portal vessels, eventually locating in internal organs where they develop into hydatid cysts, usually in the liver and/or lungs. Cysts enlarge over the life of the host and protoscoleces, the next generation of tapeworms, develop from a germinal membrane lining the cysts. Hydatid cysts of *E. gran-*

ulosus are fluid-filled unilocular structures which in humans, if left untreated, can grow to a volume of several liters and become life threatening. Lesions of *E. multilocularis*, in contrast to the large unilocular hydatid cysts of *E. granulosus*, consist of masses of small interconnected cysts (multilocular or alveolar hydatid cysts) that spread throughout the affected organ. In humans multilocular hydatidosis is often inoperable and invariably fatal if untreated. Transmission of *Echinococcus* is completed when protoscoleces are ingested by carnivores when feeding on hydatid-infected organs.

Dogs and sheep are pivotal in the transmission of *E. granulosus* in domestic situations in many parts of the world. Determining the prevalence of infection in dogs is an important means of monitoring the progress of control programs. Detection of infection in dogs has traditionally relied on a highly unreliable method, namely purging with arecoline hydrobromide and examining the purged sample for worms.

Immunology

Recent major advances have been in the use of immunological methods to diagnose infection in definitive hosts and in the development of a recombinant vaccine, highly effective in protecting sheep from hydatid infection.

Antigens

Ovine hydatid cyst fluid from fertile cysts (containing protoscoleces), and nonfertile cysts with intact germinal membranes, is the most suitable source of antigen. The highest concentration of antigen occurs in cyst fluid from fertile cysts. The major parasite antigens contained in the cyst fluid are heat-labile and heat-stable lipoproteins referred to as antigen 5 and antigen B, respectively. Antibodies against these antigens are important for immunodiagnosis of hydatid infection in humans. Antigens of *E. multilocularis* have been obtained from somatic extracts of proto-

scolec. An immunodiagnostic antigen M_r 54 kDa, obtained by immunodepletion techniques and designated EM2, has been used effectively in serodiagnosis of human alveolar echinococcosis.

Two protein antigens of M_r 27 kDa and M_r 94 kDa, derived from excretory/secretory and somatic products of protoscolec, are recognized specifically by sera from *E. granulosus*-infected dogs. Oncosphere antigens of M_r 22, 30 and 37 kDa appear to be specific to *E. granulosus* and stage-specific to oncospheres.

Expressing antigens using recombinant DNA methods is a powerful tool for antigen characterization and producing antigen in sufficient amounts for practical applications such as immunodiagnosis and vaccination. The technology is currently limited to protein antigens. A range of potentially useful recombinant clones have been made by various workers using mRNA isolated from activated protoscolec of both *E. granulosus* and *E. multilocularis* and oncospheres of *E. granulosus*.

Cellular responses to infection

There are few data regarding cellular responses against *E. granulosus* infection in dogs. *In vitro* studies indicate infection depresses the blastogenesis of some lymphocyte populations, whilst stimulating others. Most infected dogs exhibit immediate-type skin reactions to hydatid cyst fluid, but there is no delayed response.

T cells and activated macrophages are thought to be key elements in the cellular immune response against *Echinococcus* in intermediate hosts. In sheep there is a marked neutrophilia 3–5 days after infection, followed by increased eosinophil, lymphocyte and monocytes levels 25–30 days post infection. Eosinophils, lymphocytes and monocytes accumulate in large numbers in the peritoneal cavity in mice infected with *E. multilocularis* and peritoneal cells from rats with heavy infections of *E. multilocularis* kill protoscolec.

Humoral responses to infection

Dogs infected with *E. granulosus* are the definitive host studied in most detail. They produce specific circulating antibodies (IgA, IgG, IgM) against *E. granulosus* and IgG antibodies are readily detectable in sera within 2 weeks of infection. Dogs infected with closely related *Taenia* species of tapeworm produce stage-specific serum antibodies (IgG) against excreted/secreted substances of scolec and oncospheres. These antibodies become undetectable within a few weeks after the worms are lost. Antibody (IgA) against *E. granulosus* is produced by the intestinal mucosa, and elevated levels of IgE, associa-

ted with *E. granulosus* infections, are present in some dogs.

Antibodies (IgA, IgE, IgG, IgM) are produced in intermediate hosts infected with *E. granulosus*. Most studies have been carried out in humans, sheep and rodents infected with *E. granulosus* or *E. multilocularis*. In sheep the serum antibody responses against *E. granulosus* infection are weak or undetectable, whilst in humans they are easily detected and important for diagnosis.

Immunodiagnosis

Definitive hosts

Two methods (both enzyme-linked immunosorbent assays, ELISAs) have been developed for the detection of *E. granulosus* tapeworms in dogs. One detects specific circulating antibody in serum and the other parasite products (coproantigens) in feces. The sensitivity of the antibody test with sera from dogs from *E. granulosus*-endemic areas is poor, with as many as 60% of infected dogs testing negative for specific IgG antibody. Sensitivity can be improved if sera are also tested for IgE and IgM antibodies. The problems with the sensitivity of the current system make the test of little practical value for diagnosing infection in individual dogs, but the test may have some value in screening populations of dogs for recent past or current infection with *E. granulosus*.

Coproantigens of *Echinococcus* can be readily detected in the feces of infected dogs and differentiated from those of the closely related *Taenia* species of tapeworms commonly found infecting dogs (often in association with *Echinococcus*). A slightly modified version of the coproantigen test detects infection with *E. multilocularis* in foxes. The coproantigen ELISA is a very useful test because it requires no sophisticated equipment, is uncomplicated to perform and large numbers of specimens can be processed quickly. The test can be used under field conditions and shows great promise as a practical and safer means of monitoring the prevalence of dogs infected with *E. granulosus* in hydatid control programs.

The polymerase chain reaction has been used successfully to detect DNA from *E. multilocularis* eggs in feces of foxes. The method has a high sensitivity and 100% specificity, with no cross-reactions with *E. granulosus*. However, a number of foxes designated negative at necropsy were DNA positive. These apparently negative foxes may have been infected with a few worms that were overlooked.

Intermediate hosts

Detection of hydatid infection in intermediate hosts can be unreliable. Most studies have been conducted using sheep and the lack of success of immunodetection of infection in this species has been attributed to the presence of cross-reacting antibodies against related taeniid cestodes commonly infecting sheep and the relatively low titer of specific antibody produced by sheep infected with *E. granulosus*.

A variety of immunological methods have been used in the detection of hydatid infection in humans. These methods provide a useful means for primary diagnosis and monitoring patients, post treatment, for persisting or recurrent infection. Immunodiagnosis relies mainly on the detection of circulating antibodies (IgG) or parasite antigens in serum. The techniques used most commonly include ELISAs, the indirect immunofluorescent antibody test (IFAT) and immunoprecipitation tests such as immunoelectrophoresis (IEP) and immunoblotting.

As with animal intermediate hosts, problems with diagnosis of cystic hydatidosis in humans may result from the presence of cross-reacting parasite antibodies in patients infected with heterologous helminth species (e.g. *Taenia solium*). There is also evidence of false-positive antibody reactions, unrelated to parasite infections, associated with malignancies, the presence of anti-P1 blood group antibodies and liver cirrhosis.

Evasive strategies by the organism

Mechanisms by which adult *E. granulosus* evade the immune response of the definitive host are incompletely understood. The immune system of the dog recognizes the presence of the parasites and produces specific circulating antibody (IgA, IgG, IgM) against them. In addition, mucosal IgA is produced in response to the secretions of the scoleces which are in intimate contact with the mucosa. This IgA has little apparent effect on the worms, as *E. granulosus* remain in the definitive host for several years with new infections being superimposed on existing infections. It would appear that the worms have the ability to suppress the cytotoxic and effector cell activity in the region of the scolex.

The strategies by which *E. granulosus* evades the immune system of the intermediate host are complex and also incompletely understood. The adaptability of the parasite to infect many different host species exemplifies its extraordinary adaptability. *E. granulosus* is thought to manipulate the immune system of the host with various factors such as cytotoxic substances produced by cysts, mitogenic substances produced by protoscoleces, immunosuppressive and

immunostimulatory cytokines and substances capable of stimulating lymphokine production or inactivating complement.

Concomitant immunity is important in ensuring the survival of *E. granulosus* in intermediate hosts. Concomitant immunity is the ability of established hydatid cysts to avoid the immune system of the intermediate host, whilst at the same time stimulating an effective immune response against subsequent infecting organisms. The process of concomitant immunity with *E. granulosus* is thought to be antibody mediated. The mechanism is directed against oncospheres and the process of killing is thought to be antibody-dependent, complement-mediated lysis of the parasite, with killing being enhanced by the presence of neutrophils.

Vaccination

Definitive hosts

Currently, it is not possible to induce complete host-protective immunity against infection with taeniid cestodes in dogs. Reports on induced immunity against *E. granulosus* in dogs are contradictory. Vaccination studies using somatic or *in vitro* products of protoscoleces, hydatid cyst fluid or somatic preparations of whole worms induce partial protection against infection in some dogs.

Intermediate hosts

Oncospheres of *E. granulosus* have been shown to be a potent source of host-protective antigens in sheep. Using recombinant DNA methods, antigen has been expressed in *Escherichia coli* and used to vaccinate sheep, inducing high levels of protection (>96%) against experimental infection with *E. granulosus*. Use of a successful recombinant vaccine capable of protecting sheep against infection will be a useful new strategy for the control of hydatid disease in domestic livestock and potentially also in humans. However, before a recombinant vaccine can be used effectively in programs to control *E. granulosus*, more research is required in areas such as determining the duration of immunity in sheep and other intermediate hosts, protection levels in young animals and effectiveness against naturally acquired infections. Using the same technology, it should also be possible to produce a similar recombinant vaccine against alveolar hydatidosis.

ECZEMA

Jan D Bos, Department of Dermatology, Academisch Medisch Centrum, University of Amsterdam, The Netherlands

Eczema as such does not exist. It is a vague description of a variety of dermatoses with widely differing etiology, pathology and clinical manifestations. 'Dermatitis' is often used as a synonym, meaning nothing more than inflammation of the skin. Eczema as a description of skin disease is therefore always used as part of a more precise, often binominal, diagnosis. Table 1 gives a representative overview, where the 'eczemas' are etiologically classified as being (mainly) of external, combined or internal origin.

The eczemas do form a group of diseases from a dermatological *morphologic* point of view. It is their polymorphism that brings them together. Morphologically, the eczemas are characterized by ill-defined

borders, redness or erythema, vesiculation in acute stages, lichenification in chronic stages, with various forms of papulation and plaque formation, scaling, and sometimes nodule formation. Secondary infection is a common complication. The eczemas are also histopathologically similar, with an epidermodermatitis (inflammation at the epidermal–dermal region), a mononuclear (lymphohistiocytic) infiltrate and accumulation of lymphocytes that infiltrate the epidermis. Quite characteristic is the epidermal intercellular edema (spongiosis), in acute stages leading to vesicle formation.

Eczema therefore is also seen as a particular and quite common reaction type of the skin, with acute and chronic inflammation, depending on the clinical stage, and with an influx of lymphocytes into the epidermal tissue. External factors, such as ultraviolet irradiation, toxic compounds, such as in irritant contact dermatitis and eczema cracquelatum, or even superficial infestations by bacteria (microbial eczema) or yeasts (seborrheic dermatitis), are now believed to have in common a particular response pattern of the epidermis. The skin epithelium is believed to serve as a proinflammatory organ, where widely differing stimuli lead to the induction of similar keratinocyte cytokine secretion patterns, primarily of proinflammatory cytokines such as interleukin 1 β (IL-1 β), IL-6, tumor necrosis factor α (TNF α) and IL-8. Some of these cytokines upregulate adhesion molecules on dermal endothelial cells, promoting influx of leukocytes. Also, others serve as chemotactic agents, attracting these cells to infiltrate the epidermis. In such a nonspecific way, a chronic inflammatory reaction pattern is the result of widely

Eczematous drug eruption

varying provocative factors to which the skin is externally exposed.

From a specific immunologic point of view, the most interesting and intensively studied types of eczema are allergic contact dermatitis and atopic dermatitis, which will be described in more detail.

Allergic contact dermatitis

An important characteristic of skin is that it is continuously exposed to environmental influences, such as ultraviolet irradiation. Numerous microorganisms and their degradation products, organic and inorganic chemicals, and natural and artificial compounds are continuously challenging the skin's epidermal barrier. This barrier is formed by the horny layer, which is composed of corneocytes (keratinocytes that entered a programmed cell death pathway leading to cellular structures filled with keratin proteins), interspersed with a bilaminar layer of lipids and water. This lipid bilayer is the major barrier for molecular compounds, and it is generally accepted that molecules with a molecular weight over 500 Da are unable to penetrate this barrier.

Small molecules, whatever their origin, do penetrate the barrier and the skin immune system is thus continuously exposed to a substantial amount of foreign compounds. In view of the enormous amount of different chemicals and haptens and the fact that visible or abnormal skin reactions to them are rather rare, it may safely be assumed that induction of 'tolerance' is the rule and immunologic responses the exception. The explanation of this phenomenon remains one of the most challenging fundamental questions of immunology.

Allergic contact dermatitis is one of the best studied forms of delayed-type hypersensitivity and it is the result of sensitization to these small molecular compounds, also described as haptens. Molecules with a molecular weight under 500 Da are assumed to be bound by intraepidermal Langerhans cells, the major cutaneous representative of the family of dendritic antigen-presenting cells (APCs). These haptens are transported by Langerhans cells to the skin draining lymph nodes, where, in the paracortical T cell areas, induction of immunity to a given hapten may occur. It is thought that expansion of hapten-specific T cells in the lymph nodes is followed by dissemination of these T cells in peripheral blood and subsequently, perhaps through skin-specific homing, into the skin. Rechallenge of the skin then leads to elicitation of an eczema-type response, with presentation of haptens to specific T cells in the skin compartment. Well-known examples of contact allergens

are nickel, chromium, cobalt and components of cosmetics such as preservatives and fragrances.

An essential question is why certain molecules, once an individual is regularly exposed to them, give high frequencies of subsequent contact allergy, while other compounds do not have such an effect. Dinitrochlorobenzene is an example of a chemical that is able to sensitize virtually every individual exposed to it. Such a compound has an almost 100% sensitization rate and is of course abandoned from the environment. The prevalence of nickel contact allergy is estimated to be 10% in European women. Finally, there are thousands of molecules to which sensitization has occurred, but so rare that they are only published as case reports.

The sensitizing potential of different compounds thus varies widely, which implies that the induction of clonal expansion of hapten-specific T cells is rather uncommon with most chemicals and standard with just a few molecules. The question is whether it is at the level of T cells where the distinction is made, or at the level of antigen presentation. Recent research has provided arguments for the assumption that it may be the APCs' biological behavior that is decisive.

When human skin is placed in organotypic culture (*ex vivo*, *in vitro*), these specimens can be kept in culture for several weeks. In this model, it is possible to expose the corneal surface of the skin samples to different chemicals, and a major advantage is that compounds that are only soluble in diluents that are extremely toxic in cellular models can safely be applied on the corneal layer's outside surface. Using this model, it was found that known contact allergens induce the migration of Langerhans cells into the basal layers of the epidermis, and subsequently in the dermal layer. Control compounds, such as diluents, toxic compounds (e.g. sodium laurylsulfate) and known 'tolerogens' did not result in this enhanced migration pattern of Langerhans cells.

Atopic dermatitis

Atopic eczema, also known as atopic dermatitis, is a very common entity. One out of every 20 children will have an episode of atopic dermatitis during one or more periods of their lives. The disease is part of a syndrome known as atopy. It is genetically determined but the precise gene(s) responsible have not yet been identified. Other diseases that form part of atopy are extrinsic allergic asthma, rhinitis allergica, conjunctivitis allergica and certain forms of allergic food reactions. Individual patients may have any combination of these clinical entities. In many cases, atopic dermatitis takes a chronic form, with

extremely itchy eczema lesions preferentially localized in the face, the neck, elbow folds and behind the knees. Stress may exacerbate the dermatitis, as may external irritants.

The complicated and multifactorial etiopathogenesis of atopic dermatitis has resulted in different models, including entirely psychosomatic and biochemical frameworks. The dermatological entity may, however, also be described almost entirely in immunologic terminology, including genetic, biochemical, external and psychosomatic influences. The primary and dominant abnormality in atopy is the preferential synthesis of immunoglobulin E (IgE) antibodies specific for a limited set of environmental antigens. Taking that as the central stage on which atopic dermatitis develops, all other factors implied may be taken into consideration.

Genes related to atopy thus far are those located on chromosomes 11q13 and 5q31.1–3. The abnormal gene at 11q13 might be coding for the β chain of the high-affinity receptor for IgE (Fc ϵ RI). However, linkage with 11q13 could not be confirmed when, instead of asthmatics, atopic dermatitis patients were taken as probands. On 5q31.1–3, a complex of genes related to IgE production in general is localized, and its association is more with total (increased) IgE levels than with atopy. Whatever the final outcome of atopy genetics, a relationship between the genes implied and immune function seems evident.

Biochemical abnormalities include disturbances in free fatty acid metabolism (8-6 desaturase activity is decreased) and increased phosphodiesterase enzyme activity, particularly in mononuclear leukocytes. Abnormal linoleic acid content of epidermis may explain disturbances in epidermal barrier function, leading to increased irritability and subsequent pro-inflammatory activity of epidermis, as explained above. Abnormal phosphodiesterase activity leads to increased cAMP levels, and may affect T cell regulation of IgE production. Biochemical abnormalities in atopy may thus be linked to abnormal immunologic and inflammatory responses.

The central immune abnormality is production of varying amounts of IgE to a limited set of environmental antigens. It is now known that IgE production by B cells is under control of T cells, of which the T_H2 subtype stimulates B cell class switching to IgE and the T_H1 subtype inhibits such an isotype switch. This T cell-directed IgE production is realized through soluble cytokines as well as membrane interaction (CD40/CD40 ligand) signals. T_H2

cells produce large amounts of IL-4, IL-5, IL-10 and IL-13 while T_H1 cells produce large amounts of IL-2, lymphotoxin and interferon γ (IFN γ). The first human T_H2 cells were found in atopy, and it is now clear that, in atopy, patients respond to the subset of environmental antigens by expansion of specific T_H2 cells, which subsequently help B cells switching to production of allergen-specific IgE.

With all this in mind, a model of the events in atopic dermatitis-involved skin can be described. External irritants lead to upregulation of adhesion molecules through cytokine production of keratinocytes. Nonspecific influx of T cells, among them allergen-specific T_H1 and T_H2 cells, is the result. Allergen-specific IgE, present on APCs, facilitates processing of minute amounts of allergens that have reached the skin, with subsequent expansion of immigrant T cells specific for them. Interaction of released cytokines with different subsets of immunocompetent cells leads to an inflammatory reaction and, clinically, to eczema.

Many questions remain in relation to the immunopathogenesis of atopic dermatitis, but the recent advances described here are already leading to the development of novel immunotherapeutic strategies.

EFFECTOR LYMPHOCYTES

Dennis D Taub, Clinical Services Program, National Cancer Institute – Frederick Cancer Research and Development Center, Frederick, Maryland, USA
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Lymphocytes participate in a broad array of immune functions, ranging from the regulation of the functions of various leukocytic subpopulations to the antigen-specific cytotoxicity of specific target cells. Antigen-activated lymphocytes which specifically lead to the elimination of the activating antigen have been termed 'effector lymphocytes'. Classically, effector lymphocytes were defined as activated T cells possessing highly specific receptors that react with, and have the ability to destroy, specific antigens or antigen-bearing target cells. Today, the term effector lymphocyte has a much broader meaning. More specifically, lymphocytes which have been activated by antigen or nonspecifically by cytokines act upon a certain target cell population by either modulating their biological function(s) or mediating their destruction. In some types of cell-mediated immunity, antigen-specific T cells or natural killer (NK) cells directly perform their effector function by mediating the activation or lysis of specific target cells. Antigen-activated T lymphocytes can also mediate effector functions indirectly through the secretion of cytokines which recruit and activate additional effector populations that are not specific for antigen, such as macrophages and NK cells, to the site of antigen deposition. Antigen specificity is conferred to non-specific effector cells by their activation in proximity to antigen-stimulated T cells. Many different lymphocytic populations have been shown to mediate effector functions. These cells include:

1. *T cytotoxic* (T_C) cells, which are typically $CD8^+$ T lymphocytes that are capable of destroying allogeneic cells and virally-infected target cells which recognize peptide fragments in the context of major histocompatibility complex (MHC) class I molecules on the target cell surface.
2. *T helper* (T_H) cells, which are typically $CD4^+$ T lymphocytes that potentiate immunoglobulin production and isotype switching by B cells, cooperate with cytotoxic T cells in the recognition of allografts and virally-infected target

cells, and release cytokines which are capable of activating macrophages and other cell types.

3. *Natural killer* (NK) cells, which are capable of killing a number of virally-infected, transformed and allogeneic target cells to which they have not been previously sensitized.
4. *Lymphokine-activated killer* (LAK) cells, which are either T or NK cells that have been activated by interleukin 2 (IL-2) or other cytokines to enhance cell-mediated cytotoxicity of tumor, allogeneic or virally-infected target cells.
5. *T suppressor* (T_S) cells, which are typically known as regulatory cells and have been shown by some laboratories to mediate certain effector cell functions.
6. *B lymphocytes*, which, in certain instances, may modulate the activation and function of antigen-specific T cells as well as secreting specific immunoglobulin which may indirectly mediate cell-mediated cytotoxicity.

Different types of cell-mediated immune reactions may result from effector T lymphocyte recognition of antigen or a specific target cell population. Delayed-type hypersensitivity (DTH) responses are mediated by antigen-activated $CD4^+$ T cells which secrete cytokines (i.e. tumor necrosis factor α and interferon γ) that activate the local vascular endothelial cell barrier to recruit monocytes and lymphocytes to the site of antigen challenge and stimulate recruited monocytes to become activated macrophages. In cytolytic responses mediated against virally-infected target cells or allografts, or in graft-versus-host disease, antigen-activated $CD8^+$ T cells differentiate into functional cytotoxic T cells (CTLs) which lyse target cells expressing the relevant peptide-MHC complexes. This CTL differentiation process requires the presence of activating cytokines secreted by antigen-activated $CD4^+$ T helper cells. In addition, NK and $CD8^+$ T cells stimulated by cytokines secreted by antigen-activated $CD4^+$ T cells differentiate into LAK cells which nonspecifically lyse target cells.

ELECTRON MICROSCOPY, IMMUNOLOGICAL APPLICATIONS

Matthew A Gonda, Laboratory of Cell and Molecular Structure, SAIC Frederick, National Cancer Institute – Frederick Cancer Research and Development Center, Frederick, Maryland, USA

Historical background

The potential for employing labeled antibodies to localize antigens or antibodies in tissues at the microscopic level was first conceived by and realized through the experiments of Coons and colleagues in 1941 and 1942. These experiments described the first immunoconjugates wherein antibodies were chemically coupled to fluorescein and used to specifically bind target antigens in tissues. The resultant ‘microprecipitates’ were identified by their brilliant green color in a light microscope equipped with an ultraviolet light source and appropriate excitation and emission barrier filters for fluorescence microscopy. Novel fluorochromes such as rhodamine, Texas red and phycoerythrin have since been discovered that can be coupled to antibodies which, when excited by the appropriate wavelength of ultraviolet light, can be identified by their red color. The ability to couple fluorochromes with distinct emission spectra to antibodies specific for different epitopes has permitted dual-antigen localizations on the same sample. In addition to immunofluorescence microscopy, enzymes have also been coupled to antibodies and used to localize the antibody–antigen interaction. In immunoenzyme microscopy, the antibody-coupled enzyme converts a colorless chromogenic substrate into colored end-products at the site of the antibody–antigen reaction, which can then be visualized by conventional light microscopy.

With the advent of the transmission electron microscope and its greater resolving power, now in the range of 0.14 nm, valuable approaches complementary to those employed for the light micro-

scope were developed to localize specific antigen at the ultrastructural level. The first such immunoconjugates for electron microscopy utilized electron-dense molecules to replace the fluorochromes used in the ultraviolet microscope. Singer was the first, in 1959, to develop a method for coupling an electron-dense molecule, horse-spleen ferritin, to antibodies without a concomitant loss of immunobinding capacity. The experimental results of Rifkind and colleagues conclusively demonstrated in 1960 the utility of these electron-dense ferritin–antibody conjugates in the immunodetection of antigens in the electron microscope. These experiments formed the early foundation for the field of study now known as immunoelectron microscopy.

Principles of immunoelectron microscopy

Immunoelectron microscopy can be defined as any technique that uses antibodies, or molecules that interact with antibodies (for example, protein A or protein G), in conjunction with electron microscopy to localize ultrastructurally antigens or antibodies in cells and tissues. In addition, a number of other biological macromolecules whose specific ligand-binding properties are known can be used (for example, lectins). Immunoelectron microscopy was a term that was originally confined to studies that made use of the transmission electron microscope but now include those that use the scanning electron microscope.

In the transmission electron microscope, electrons serve as a pseudo-light source. High-energy electrons

emitted from a filament are accelerated and forced by electromagnets into a very fine coherent beam in the center of the microscope column. Because electrons are used, the microscope column and specimen area are maintained in a vacuum (10^{-6} – 10^{-8} Torr) to prevent the deflection of electrons by atmospheric gases. The electron beam is focused on to the sample. Here, the more electron-dense molecules in the sample under observation adsorb and scatter electrons, preventing their passage through the sample. Those electrons with enough energy to penetrate are transmitted, further focused, and projected on to a phosphor screen. The image is resolved on the phosphor screen due to the emission of photons in the area struck by the transmitted electrons. The image can be permanently recorded directly on photographic film sensitive to electrons or visualized with photographic cameras interfaced with the electron microscope viewing chamber and a computer to rapidly generate high-resolution computer processed images.

In preparation for transmission electron microscopy, samples are usually fixed with aldehydes (glutaraldehyde, formaldehyde or a combination of the two), post-aldehyde fixed in osmic acid, *en bloc* stained with a uranyl acetate solution, dehydrated with alcohols and embedded in a plastic resin. The embedded samples are thin sectioned with a glass or diamond knife and subsequently counterstained with heavy metals (uranium and lead salts) to further enhance the electron density of positively or negatively charged molecules in the sample. Specimens thus prepared have good contrast and can be used to observe and record the molecular and subcellular detail of cells and tissues. Alternatively, molecules may be adsorbed to a thin plastic film followed by embedding in an electron-dense stain or angular shadowing with evaporated metals.

The mechanical principles of operation for the scanning electron microscope are virtually the same as for transmission electron microscopes. The major difference is in the formation of the image. In scanning electron microscopes, the focused electrons are scanned over the surface of a sample, as implied by the name. Instead of transmitting electrons, secondary electrons emitted from the interaction of electron beam and sample are collected, electronically deciphered and multiplied, and projected on to a high-resolution cathode-ray tube. These images give a quasi three-dimensional impression of the structure under observation because of the great depth of field of the scanning electron microscope. The image is recorded on film using an ordinary camera focused on the cathode-ray tube. Samples for scanning electron microscopy must be fixed and dehydrated, as in transmission electron microscopy, but instead of

embedding the sample in a plastic resin, it is covered with a conductive coating of a fine metal, such as gold, by evaporation; no further processing is necessary.

As some examples of the utility of these techniques in ultrastructural research, transmission electron microscopy can reveal the structure of macromolecules adsorbed to a film, the surface detail of samples through surface replicas, or the internal structure of cells or infectious agents through thin sections. Scanning electron microscopes are primarily used for observing the surface detail of cells and tissues. The incorporation of immunoconjugates or other ligands into electron microscopic studies permits the high-resolution study of the antigenic composition of cell organelles and surfaces in concert with ultrastructural analyses. Singularly, or in combination, these two types of microscopic analysis have proved invaluable in the correlative study of morphologic structures and their antigenic composition.

Markers for immunoelectron microscopy

Native antibodies or their functional subunits have been used in the absence of a marker in some applications. However, most applications require a morphologic or electron-dense marker to visualize the antibody–antigen microprecipitation. Many marker systems have been developed for immunoelectron microscopy. The markers in these systems fall into several major categories: electron-dense biological molecules such as ferritin, colloidal-gold sols, enzymes that produce an electron-dense product, synthetic microspheres, and biological molecules with a distinct morphologic shape (hemocyanins, bacterial, animal and plant viruses, etc.). The choice of marker depends primarily on the application. A marker system which renders the microprecipitation site electron dense or morphologically recognizable is preferable for transmission electron microscopy. **Figure 1** shows a gallery of markers used in transmission immunoelectron microscopy to localize retroviral envelope glycoproteins.

Morphologically recognizable markers such as viruses, latex microspheres and hemocyanins have the greatest utility in scanning electron microscopy, where electron density plays less of a role because of the metallic coatings that are applied for imaging with secondary electrons. Moreover, the markers for scanning electron microscopy must be larger than those required for transmission electron microscopy and have a distinct and uniform shape and size to be easily resolved against the topographical features of the cell surface and the lower resolving power of

Figure 1 Gallery of indirect immunoelectron microscopic methods used to demonstrate the reactivity of an antiretrovirus envelope glycoprotein goat serum on the envelope of virus particles and the physical characteristics of the various markers as observed in the transmission electron microscope. (A) Virus-infected cells in which the primary serum was a normal goat serum, as used with any of the marker systems presented in (B–F). The primary serum in (B–F) was the antiretrovirus envelope glycoprotein goat serum; in each frame the primary antibody was localized by one or more secondary antibodies that brought an electron-dense or morphologically visible marker into the proximity of the microprecipitation. scanning electron microscopes. Where correlative studies require the use of transmission and scanning electron microscopy, a marker resolvable by both transmitted and secondary electrons must be selected; hemocyanins and viruses are especially useful in this scenario. **Figure 2** shows the use of the hemocyanin marker in the localization of the surface glycoprotein of a retrovirus by scanning and transmission immunoelectron microscopy, for comparison.

Immunoreagents

Polyclonal antisera that contain a mixture of antibody populations and monoclonal antibodies are the most commonly used reagents in immunoelectron microscopy where antigen (or antibody) is being localized. Immunoglobulin G (IgG) in serum fractions is most often preferred, unless the reaction considerations specify otherwise. Purity and specificity of polyclonal antisera can be improved by affinity purification steps. The benefits of monoclonal anti-

body use are well known. There are also several bacterial cell wall proteins, protein A and protein G, that bind the Fc portion of γ -globulin from various species and have proven useful in detecting antibody bound to antigen. Moreover, since protein A and G are proteins, they can be conjugated to markers useful in immunoelectron microscopy and applied to the detection of a variety of γ -globulin classes from multiple species. Other types of biological macromolecules (e.g. lectins, asialoglycoprotein, etc.) unrelated to antibodies, when conjugated to markers, can be used as ligands to localize ligand-receptor interactions because of their known specificity and affinity for target molecules. Two other macromolecules, streptavidin and biotin, have been used in immunconjugates because of their high affinity and specificity for each other. In this case, biotin is used to directly label the specific antibody and streptavidin is conjugated to the marker. The strong interaction between streptavidin with biotin brings the marker into contact with the bound antibody.

Antibodies can be coupled to the marker by various methods. The most common method, when two protein molecules are involved, is to conjugate the antibody to the marker chemically via a low molecular weight bifunctional coupling reagent (e.g. glutaraldehyde, metaxylylene di-isocyanate, thiocarbamide, etc.). However, in the case of highly charged metal sols, like colloidal gold, the electrostatic forces of this material can be used to irreversibly bind antibodies, protein A and G, or streptavidin molecules to the gold particulate.

Direct and indirect labeling approaches

There are two basic approaches to labeling target antigen with the immunoconjugate; they are the direct and indirect techniques (Figure 3). The direct method is the simplest and involves the use of specific antibody conjugated to the marker to localize its target antigen in a one-step procedure. In the indirect test, a two-step procedure is employed. An unlabeled-specific antibody, called the primary antibody, is used to bind to the target antigen. The unlabeled-specific antibody complex is localized with a marker-conjugated anti-immunoglobulin, called the secondary antibody. The indirect technique is sometimes called the 'sandwich technique'. In the case where an enzyme such as horseradish peroxidase is conjugated to the primary or secondary antibody, the immunoprecipitate is reacted with enzyme substrate and developer for contrast (see Figure 1C for an example of the indirect immunoperoxidase technique).

There are various themes of these two labeling techniques. One indirect labeling method worth

mentioning is the unlabeled antibody bridge method (Figure 3H), which involves four steps, but can be used in correlative transmission and scanning immunoelectron microscopy. Using the unlabeled antibody hemocyanin bridge as an example, unlabeled specific antibody (e.g. rabbit IgG) is first reacted with substrate. An unlabeled bridging antibody (rabbit-specific IgG), which was raised to the immunoglobulin species of the specific antibody, is then bound. A third antibody to marker, hemocyanin, made in the same species as the specific antibody, is then applied and bound by the free Fab arm of the bivalent bridging antibody (rabbit-specific IgG). Hemocyanin is then applied and bound by the free Fab arms of the marker-specific antibody (third antibody in the bridge). Figures 1E and 2 are examples of the unlabeled antibody hemocyanin bridge used to localize retroviral antigens.

Immunolabeling techniques

Immunolabeling techniques for transmission electron microscopy can be divided into three basic categories: no embedding, pre-embedding and postembedding. The no-embedding method is used primarily for immunostaining large biological molecules, such as proteins and nucleic acid-protein complexes, viruses, and frozen cryostat sections mounted on film-coated grids that need no further fixation or intramolecular supporting matrix. The pre-embedding technique is used for labeling cell surfaces (see Figures 1 and 2). This technique does not readily permit access to intracellular antigens. In the pre-embedding technique, unfixed or mildly fixed material is immunostained before the embedding and sectioning processes. In the postembedding method, the material is lightly fixed, embedded and thin sectioned. The thin sections are then immunostained. Figure 4 shows an application of the postembedding method in localizing an intracellular protein. This methodology is the most versatile in visualizing intracellular structures and associated antigens simultaneously and has overcome the many problems incurred by other methods. Since mild fixation and embedding are required in the postembedding thin-section immunostaining method, it should be noted that a number of potential problems can be encountered, including a reduction in immunogenicity, accessibility and concentration of target antigen, during the embedding process, and a loss of ultrastructural definition due to the mild fixation procedures.

All immunolabeling techniques for scanning electron microscopy are performed before dehydration and application of a conductive coating to reveal sur-

Figure 3 Direct (A–C) and indirect (D–H) immunologic labeling techniques used to localize antigens for immunoelectron microscopy. *Direct methods.* (A) Marker is conjugated to primary antibody (IgG) and (B) to Fab fragment. (C) Renatured hybrid $F(ab)_2$ fragment with dual specificity bridges target antigen and marker. *Indirect methods.* (D) Marker-conjugated secondary antibody (IgG) binds unlabeled primary antibody (IgG). (E) Marker-conjugated protein A binds unlabeled primary antibody (IgG). (F) Marker-conjugated streptavidin binds biotinylated primary antibody (IgG). (G) Biotinylated secondary antibody (IgG) bridges marker-conjugated streptavidin and unlabeled primary antibody (IgG). In the unlabeled antibody bridge method (H), unlabeled secondary antibody (IgG) bridges unlabeled tertiary antibody (IgG) to marker and unlabeled primary antibody (IgG) to target antigen; marker is bound by tertiary antibody (antibody to marker). Figure 4 Electron micrograph of natural killer (NK) tumor target (T) cell conjugates 30 min after initial interaction. The post-embedding thin-section immunolabeling method was used to localize an intracellular pore-forming protein believed to have an active role in target cell lysis. Thin sections were labeled with monoclonal antibodies to pore-forming protein and bound antibodies were localized by the indirect immunogold method. The arrows in the NK cells depict the effector granules containing colloidal-gold-labeled pore-forming protein. Scale bar = 1.0 μm . (Micrograph contributed by J Ortaldo, K Nagashima and MA Gonda.)

face detail. Samples may be fixed or unfixed before the labeling. Often it is desirable to fix the sample mildly with dilute solutions of glutaraldehyde (0.1–0.25%) before labeling, especially where the labeling procedure may alter the surface architecture under investigation.

Future of immunoelectron microscopy

Applications of immunolabeling procedures can be found in many scientific disciplines involving ultra-structural studies of biological structure and function. The use of labeled immunological probes in conjunction with electron microscopy has made many contributions to our overall understanding of the antigen composition and structure of cells and tissues in various pathologic states. In addition, immunoelectron microscopy has helped to resolve the structure of pathogens and understand

pathogen–host interactions in various disease states. Although immunoelectron microscopy in the strictest sense implies that antibodies are used, there are a variety of other macromolecules that have been used in studies of receptor–ligand interactions. No doubt, with advances in molecular biology, the discovery, definition and availability of new ligands will continue at an increasing pace and be used in localization studies by electron microscopy. The use of immunoelectron microscopy, aided by highly specific monoclonal antibodies and genetically engineered probes, will continue to advance our knowledge of cellular and molecular structures and be an important tool in immunocytochemistry and histopathology.

ELISPOT ASSAY

Jonathon D Sedgwick, Centenary Institute of Cancer Medicine and Cell Biology,
Royal Prince Alfred Hospital, Camperdown, Sydney, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Detection of soluble products secreted by cells of the immune system, particularly immunoglobulin (Ig) and cytokines, remains one of the cornerstones of immunological inquiry at both the clinical laboratory and research laboratory levels. The most sensitive methods for this purpose are those that detect secreted products of a single cell. The enzyme-linked immunospot (ELISPOT) assay is an ELISA-based technique that enables detection and enumeration of Ig- and cytokine-secreting cells at the single cell level. The assay is now applied to wide-ranging immunological investigation.

The immune system can very broadly be divided into two parts – cell-mediated immunity and humoral immunity. To some extent, each arm of the immune response is influenced by or dependent on the other. For example, CD4⁺ T lymphocytes (part of the cell-mediated immune system) respond to a viral infection by liberating factors (lymphokines or cytokines) which help B lymphocytes (broadly part of the humoral immune system) to differentiate into plasma cells. These cells secrete specific immunoglobulin (antibody) which may neutralize the virus. It is evident from this rather simplistic view of T–B lymphocyte interaction, that substances secreted by both cell types are central to the effective operation of the immune system. Thus, for many years, immunologists have been interested in quantifying and further characterizing these secreted molecules.

One of the most widely used *in vitro* assays for the detection of antibody in solution is the enzyme-linked immunosorbent assay (ELISA), first described in 1971. The ELISA utilizes the fact that many substances (such as protein antigens) nonspecifically adsorb to plastic surfaces and that specific antibody (for example in serum) can bind to this immobilized antigen and subsequently be detected by a second immunoglobulin-specific antibody which is coupled to an enzyme such as alkaline phosphatase or peroxidase. A substrate solution is added to this immobilized antigen–antibody complex which yields a soluble colored product in the presence of the enzyme. The intensity of the color of this solution is related to the amount of antibody bound to the antigen. From this, the concentration of antibody in the original serum sample can be determined.

The ELISA is not limited to the detection of antibody. Following the availability of monoclonal and

polyclonal antibodies specific for cytokines, ELISAs have now been developed for a range of factors secreted by cells such as T lymphocytes and macrophages. In this case, however, a cytokine-specific antibody rather than antigen is coated on to the plastic surface. The cytokine-containing solution (such as supernatant from *in vitro* activated T lymphocytes) is added followed by a second enzyme-labeled cytokine-specific antibody and substrate.

Notwithstanding the usefulness of assays such as ELISA for the detection of substances in solution, greater definition and sensitivity may be obtained by employing methods which enable one to detect secretion of immunoglobulin or cytokine at the single cell level. The first method to be described for the detection of single immunoglobulin secreting cells (ISCs) was the hemolytic plaque-forming cell (PFC) assay. This technique has served immunologists well since its description in 1963 but there are some circumstances in which the PFC assay is suboptimal in its sensitivity and specificity. Moreover, only limited success has been achieved with the PFC assay as a means of detecting cytokine secreting cells (CSCs).

The obvious advantages of the ELISA for the detection of low levels of antibody prompted the development of an ELISA-based system for the detection of ISCs and, more recently, for CSCs (Figure 1). The ELISPOT assay was developed by two groups and details of the technique published in 1983. This technique has now all but replaced the hemolytic PFC assay. The assay goes under a number of names which include those in the original descriptions (ELISA-plaque and ELISPOT assays) as well as SPOTELISA and ELISASPOT. However, the term ‘ELISPOT’ is now most commonly used and is widely recognized as defining a unique and distinct assay system. As illustrated in Figure 1, the assay is similar to a standard ELISA but with two important differences. First, cells are added rather than a solution and second, the substrate chosen for the ELISPOT yields an insoluble product. Thus, substrate precipitates at the site of enzyme activity which is localized at the point where antibody or cytokine was secreted. This ‘fingerprint’ of the secreting cell is revealed as a colored spot and can readily be counted.

As with the standard ELISA, there are a number of ways in which the basic method illustrated in

Figure 1 The ELISPOT assay. (A) Added cells secrete immunoglobulin or cytokine which binds locally to antigen or is captured by antibody bound to the plastic or nitrocellulose solid phase. (B) Cells are removed. Locally secreted product is detected by enzyme-linked antibody specific for immunoglobulin or cytokine. (C) The site of immunoglobulin or cytokine secretion is revealed by addition of enzyme substrate that yields an insoluble colored product. (D) Colored spots represent the secreted product of a single cell and can be counted by eye or under low magnification.

Figure 1 may be altered. For example, ELISPOT assays have now been performed using biotin-labeled antibody together with avidin-labeled enzyme. A further refinement is the use of antibody/enzyme/substrate combinations that enable detection of two distinct Ig isotypes simultaneously, by virtue of different colored substrate products.

One of the most important aspects to optimize in the ELISPOT assay is the solid phase which consists of the combination of vessel surface and coated antigen or antibody. Relatively high levels of some antigens, for example ovalbumin, are required when coating plastic surfaces while other molecules such as purified Ig effectively coat the plastic surface at concentrations 10–20-fold less than is required for ovalbumin. Capture antibody (i.e. coated Ig) is therefore a useful alternative and is mostly used when one wishes to detect ISCs of no particular antigenic specificity (total ISCs) or for the detection and enumeration of cells secreting factors such as cytokines.

For the detection of antigen-specific ISCs where antigen is only available in small amounts (for example, purified viruses) or does not bind readily to plastic, other modifications have been introduced. The first is the use of nitrocellulose rather than plastic in the floor of the assay vessel. Nitrocellulose has a much greater capacity to bind protein than plastic and so the efficiency of antigen binding is substantially increased. A second modification is the labeling of the antigen in such a way that binding to the plastic surface is unnecessary. For example, the plastic surface can be coated with avidin and biotinylated antigen added. Alternatively, it is possible to use antigen directly coupled to an enzyme. The plastic surface is coated with an isotype-specific capture antibody which binds all antibody of a particular isotype secreted by the added ISCs. Antigen specificity is achieved by adding the enzyme-coupled antigen which is bound only at the localized sites where antigen-specific immunoglobulin was secreted and captured.

The range of specificities of ISCs now detected in both experimental animal systems as well as in humans is considerable and varies from commonly used antigens such as ovalbumin and haptens to viruses and insulin and molecules of importance in autoimmunity such as thyroglobulin, myelin basic protein and rheumatoid factor. ISCs specific for particulate antigens including platelets, sheep erythrocytes and whole bacteria as well as purified bacterial antigens such as polysaccharide have also been enumerated. There is no apparent limitation on the antibody isotype that can be detected and the discriminating power of the ELISPOT assay means that ISCs

present at very low frequency (such as IgE-ISCs) can now be examined readily.

Successful detection of cells secreting a range of cytokines has been achieved, and includes those producing interleukin 1 α (IL-1 α), IL-1 β , IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, interferon γ (IFN γ) and tumor necrosis factor (TNF). Direct comparisons between ELISA and ELISPOT assays for cytokine production by T cell clones *in vitro* has indicated that the ELISPOT assay for CSCs is between 10 and 200 times more sensitive than cytokine detection by ELISA performed on culture supernatant. CSCs directly *ex vivo* as well as after *in vitro* stimulation have been used successfully in the ELISPOT assay attesting to the versatility and utility of the technique.

In conclusion, the ELISPOT assay is a simple, versatile yet powerful technique for the detection and enumeration of cells liberating Ig or cytokine. The technique can be modified in a variety of ways to suit individual needs and circumstances and to optimize sensitivity. Its application to the detection of cells secreting molecules other than Ig or cytokine should also be considered. The detection of bone marrow-derived mast cells secreting mast cell protease II, is one published example of an alternative application for the ELISPOT assay.

EMBRYONIC ANTIGENS

Matteo Adinolfi, The Galton Laboratory, Department of Genetics and Biometry, University College London, London, UK

During embryonic and fetal life, unique proteins and carbohydrates are synthesized which are either absent or are produced only in very small amounts in normal adult individuals. Studies of these 'embryonic' and 'fetal' molecules have been crucial in the formulation of many concepts in the field of molecular genetics, and particularly in the identification of the processes responsible for switching on and off

genes during development. Interest in embryonic and fetal molecules also derives from their persistence or reappearance in certain disorders. Thus abnormalities involving the rate of synthesis of adult hemoglobin (Hb) chains (α or β) affect the regulation of embryonic and fetal Hb genes. For example, in fetuses with α -thalassemia, due to deletion of both the α -chain genes, hemoglobin, Bart's (γ_4), Hb H (β_4)

and embryonic Hb Portland ($\zeta_2\gamma_2$) continue to be produced.

Blood group antigens provide another example of fetal molecules that can be expressed in adults in various conditions. Red cells of almost all healthy adults carry the blood group antigen 'I' and very small amounts of 'i'. In contrast, fetal red cells react strongly with anti-i sera and weakly with anti-I. Using anti-i, increased agglutinability of red cells from adult subjects is seen in patients with thalassemia and hypoplastic anemia, while high levels of cold autoagglutinins with anti-i specificity are often detectable in patients with infectious mononucleosis.

Fetal proteins such as alphafetoprotein (α -fetoprotein, AFP) and carcinoembryonic antigen (CEA) are synthesized once again in large quantities in patients with selected tumors, and their estimation, by immunologic techniques, has proved to be a diagnostic and prognostic index of the disease.

Only a few fetal proteins of particular interest to immunologists, either because they are detected using immunologic techniques or for their presumed immunoregulatory function, will be described.

α -Fetoprotein

In 1956, human fetal sera were shown to contain a protein apparently absent in sera from normal adult individuals. A similar protein, termed α -fetoprotein (AFP) and shown to be structurally distinct from bovine fetuin, was later detected in all mammalian species investigated.

AFP appears early during human development; in fact, traces of this protein have been detected in 4-week-old embryos. The AFP plasma levels increase rapidly during the first trimester of gestation, reaching the highest values ($2\text{--}3\text{ mg ml}^{-1}$) around 12–16 weeks and later declining. In cord blood the AFP levels are usually below 0.2 mg ml^{-1} ; traces of the protein ($>20\text{ ng ml}^{-1}$) can be detected in sera from normal adults (Figure 1).

Human AFP has a molecular weight of approximately 66 kDa and a carbohydrate content near 3.5%. In all species investigated, AFP is structurally similar to albumin. In fact, a highly conserved pattern of gene organization, similar to the albumin gene, is evident. In humans, both the AFP and albumin genes, which comprise 15 exons separated by 14 intervening introns, map on chromosome 4.

Besides being present in plasma, AFP can be detected in most fetal fluids such as amniotic and cerebrospinal fluids (CSF) and urine. Small amounts of AFP cross the human placenta and increased levels (up to 500 ng ml^{-1}) of this protein are present in sera from normal pregnant women.

Figure 1 Synthesis of AFP in human fetal liver (A) compared with the levels of the fetal protein in fetal sera (B), amniotic fluid (C), and maternal sera (D). The concentration of AFP in maternal sera increases with gestation, due to the increased permeability of the placental barrier.

Abnormally high levels of AFP in amniotic fluid and maternal sera are associated with fetal neural tube defects (NTDs), such as anencephaly and open spina bifida. This results from the still immature blood–CSF barrier, which allows transfer of AFP from serum firstly into the CSF, and then into the amniotic cavity. Congenital abnormalities, other than NTDs, associated with high levels of AFP in amniotic fluid are shown in Table 1. On the other hand, abnormally low maternal serum levels of AFP during the first trimester of gestation are indicative of fetal chromosome trisomies (e.g. trisomy 21, the Down syndrome).

The discovery that the serum levels of AFP are greatly increased in patients with primary cancer of the liver has prompted a series of investigations which have documented the diagnostic and prognostic value of estimating the AFP plasma levels in such

Table 1 Some congenital abnormalities, other than neural tube defects, associated with abnormal values of α -fetoprotein

High levels in amniotic fluid:
hydrocephalus

congenital esophageal atresia
exomphalos
Low levels in amniotic fluid:
Down syndrome

patients. Synthesis of AFP also increases during liver regeneration; thus abnormal levels of this protein suggest liver damage and repair. High levels of AFP have been detected in patients with teratocarcinoma and ataxia telangiectasia.

During the past 20 years, several investigators have focused their attention on the possible role of AFP as an immunosuppressive factor. Early reports suggested that AFP, partially purified from rodent and human fluids, would suppress the mitogenic effects of phytohemagglutinin, concanavalin A and lipopolysaccharide on spleen cells or lymphocytes, as well as inhibiting lymphocyte stimulation in the one-way mixed lymphocyte reaction.

Other investigators have not been able to confirm these findings nor to demonstrate the presence of specific AFP receptors on the surface of normal lymphocytes, as previously claimed. In addition, fetal mouse and human sera, containing high levels of AFP, have been repeatedly shown not to exhibit *in vitro* immunosuppression. In conclusion, the discrepancies of the experimental results and theoretical considerations do not support the claim that AFP has a major role as an immunosuppressive agent.

Carcinoembryonic antigen

Carcinoembryonic antigen (CEA), described by Gold and Freedman in 1965, was the first and most widely used plasma tumor marker. Like AFP, it belongs to the so-called 'oncofetal' antigens, which are normally found in fetal tissues and plasma but are present only in very small quantities in normal adult subjects.

It has been shown that CEA consists of a group of proteins of between 175 and 200 kDa, containing up to 50% carbohydrate, whose immune reactivity resides on the protein moieties. Early studies suggested that high levels of CEA are produced by fetal colon and colon carcinoma cells and that only small amounts of CEA are present in plasma from normal adult subjects (upper limit between 5 and 20 ng ml⁻¹; subsequent investigations have shown that abnormally high levels of CEA are also produced in patients with primary and secondary can-

cers of the liver, breast and ovarian tumors, and occasionally in patients with acute or chronic hepatic disease. Modest elevation of CEA has been detected in patients with colitis.

The general view is that CEA tests display adequate sensitivity but very poor specificity, and thus plasma estimation of this antigen is of little value in screening high-risk groups or asymptomatic individuals. Adding to the clinical problems, there are also technical difficulties associated with the immunologic techniques employed to estimate CEA plasma levels owing to interassay variability.

Common acute lymphoblastic leukemia antigen (CD10)

Originally identified on the surface of acute lymphoblastoid leukemia (ALL) cells and designated as common acute lymphoblastoid leukemia antigen (CALLA), the antigen has now been assigned the cluster of differentiation number 10 (CD10). CALLA was initially recognized using rabbit antiserum raised against ALL cells which had been precoated with rabbit antibodies against antigenic determinants present on normal lymphocytes. The rabbit anti-CALLA sera were found to produce a maximal reactivity against peripheral blood nucleated cells from ALL patients, and a minimal reactivity when tested against normal bone marrow cells or cells from patients with leukemias other than ALL. Using monoclonal antibodies, the distribution of CALLA⁺ cells has been further clarified. Thus very few CALLA⁺ cells are present in peripheral blood samples from normal individuals, while CALLA⁺ cells, coexpressing immunoglobulin M (IgM) molecules and CD19, are detectable in fetal bone marrow and peripheral blood samples. CALLA⁺ fetal bone marrow cells, cultured with interleukin 2 (IL-2) and irradiated feeder thymocytes can differentiate to CD2⁺, CD3⁺ cells expressing either CD4 or CD8. These findings are consistent with early data suggesting that CALLA molecules are expressed on B and T cells during early stages of fetal development. CALLA⁺ cells are detectable in a majority of patients with B-ALL, in a proportion of T-ALL patients and in some cell lines derived from T cell non-Hodgkin lymphoma (T-NHL). The antigen is expressed in about one-third of Ph⁺ chromosome-positive leukemia patients during blast crisis.

The molecular nature of CD10 has now been partially defined; cDNA clones have been isolated, sequenced and shown to control the synthesis of

a protein structurally identical to the human membrane-associated enzyme neutral endopeptidase (NEP 3.4.24.11).

The biological enzymatic role of CD10 molecules has not yet been clarified, but it has been suggested that CD10-NEP mediates chemotaxis and that the presence or absence of CD10-NEP might affect the clinical course of ALL in childhood. It seems, in fact, that CD10⁻ patients with ALL have shorter disease-free survival.

Elucidation of the biological function of CD10 molecules expressed on subpopulations of lymphocytes during fetal life and in patients with leukemia might only be obtained once the specific substrate of this enzyme has been identified.

Other 'fetal' antigens

Occasionally fetal antigens are claimed to be expressed on cancer cells, but in several instances these antigens are also present in some normal adult tissues and, accordingly, their presence in cancer cells is the result of an ectopic gene expression. 'Fetal' antigens have been claimed to be present in amniotic fluid, including several acid glycosphingolipids; however, the biological and biochemical properties, as well as the site of synthesis, of these factors are still uncertain. A fetal form of acetylcholine receptor (AChR) has been postulated to exist because maternal antibodies have been detected that specifically inhibit AChRs in the fetus and the newborn, but not in the mother, and are responsible for the syndrome termed arthrogryposis multiplex congenita.

Finally, it should be mentioned that immunologic methods have been found useful for localizing antigens to different parts of a tissue during adult or embryonic and fetal life. For example, immunohistochemical tests have shown that, during embryogenesis, lactase is present in different portions of the intestine to where it is found in the adult tissue. However, no structural differences of this enzyme have been observed.

Immunologic tests have also been successfully employed to evaluate quantitative differences of gene expression between adult and fetal cells. However, recently, the detection of mRNA has been more widely used to detect and quantify gene expression and the role that transcription factors play in terminal differentiation of stem cells into defined mature cell types.

Recently, antibodies against fetal Hb (Hb F) have been used to detect, and eventually isolate, fetal erythroblasts present in maternal peripheral blood samples. However, since a few erythroblasts are also

released in normal adults and, more frequently, during gestation, the fetal origin of such cells should be established by the detection of other fetal markers, such as the presence of a Y chromosome by fluorescent *in situ* hybridization if the fetus is male.

ENDOTHELIUM

Alberto Mantovani and **Elisabetta Dejana**, Department of Biomedical Science and Biotechnology, University of Degli Studi Di Brescia, Brescia, Italy

Endothelial cells have long been perceived as a 'sheet of nucleated cellophane', a 'passive' lining of vessels, endowed with negative properties, the most crucial one being that of representing a nonthrombogenic substrate for blood. As such, endothelial cells were viewed to participate in tissue reactions essentially as targets for injurious agents. In the last few years, endothelial cells have emerged as active participants in a variety of physiologic and pathologic processes. In particular, the ontogeny and function of white blood cells requires an intimate relationship with vascular endothelial cells. The endothelial cells are an important constituent of the hematopoietic microenvironment of the bone marrow and produce colony-stimulating factors (CSFs) which regulate hematopoiesis. The recirculation and homing of lymphocytes is accomplished via interaction with endothelial cell structures and these cells can activate specific immunity by presenting antigen. Finally, the effector arm of immunity, inflammatory reactions and hemostasis involve close interactions between leukocytes and vascular cells.

Endothelial cell-to-cell junctions

Circulating cells infiltrate into tissues by migrating through intercellular junctions. These organelles are formed by a complex network of transmembrane proteins linked to a well-developed plasmalemmal undercoat. One of the typical characteristics of endothelial junctions is their dynamic organization. Endothelial cells are able to change rapidly the architecture of the junctions to allow the passage of circulating blood cells. This effect, in most cases, is quickly reversible and the endothelium is able to disorganize/reorganize its intercellular junctions within minutes. Interendothelial junctions present a different degree of complexity along the vascular tree responding to different functional requirements. For instance, they are well organized and numerous in large arteries or in the blood vessels of the brain

where the control of permeability must be strict, whereas they are very primitive in the postcapillary venules, where cell extravasation and exchange of plasma constituents need to be particularly efficient. On the basis of morphologic and functional characteristics at least four types of junctions have been described in endothelial cells. These are: tight junctions, adherence junctions, gap junctions and syndesmos.

Although there is a great deal of information regarding the molecules that mediate leukocyte adhesion to the endothelium, the mechanisms by which leukocytes trigger the opening of endothelial cell junctions is still obscure. In many conditions the passage of leukocytes through endothelial junctions does not increase endothelial permeability *per se* or cause vascular damage.

Chemoattractants and adhesive molecules stimulate neutrophils to secrete oxygen-free radicals, lipid metabolites and proteases, each of which is a potential agonist of endothelial permeability. However, experimental evidence suggests that these reactive agents are not necessary for neutrophil extravasation. The question of how leukocytes pass through endothelial clefts remains open. An interesting possibility is that leukocyte adhesion to endothelial cells causes a cascade of events similar to that induced by soluble agonists of endothelial permeability. In particular, leukocyte ligation to endothelial adhesive molecules (such as selectins, VCAM-1 or ICAM-1) could generate intracellular signals similar to those caused by permeability-increasing agents. It has been found that endothelial cells respond to neutrophil contact and migration by increasing intracellular calcium and inhibitors of intracellular Ca^{2+} block neutrophil transmigration. In addition, ICAM-1 activation by specific antibodies leads to phosphorylation of the actin-binding protein cortactin. This or other signals could induce changes in cleft molecular organization (see above), leading to the opening of gaps between

endothelial cells. According to this hypothesis endothelial cells would not only play an important role in regulating leukocyte attachment to their surface but also actively modulate their extravasation.

Leukocytes might find preferential pathways for their passage through the interendothelial clefts. Tight junctions and adherence junctions comprise a system of discrete ion-selective pores rather than an absolute seal around the cells. In endothelial cells, the presence of areas of junctionless clefts that regulate the transendothelial transport of high molecular weight proteins has been described. Leukocytes might be directed to these pores through the concentration gradient of specific adhesive molecules such as CD31. Their passage would require them to squeeze through the pores, accompanied by rearrangement of the endothelial cell cytoskeleton organization around these structures.

There might be differences between the modalities of leukocyte extravasation for different types of vessels where the clefts present different levels of complexity. There might also be distinct mechanisms regulating the passage of the different types of leukocytes or of other types of cells.

Endothelial cell adhesion molecules

The recruitment of leukocytes into sites of inflammation involves a cascade of sequential events controlled by the interaction between adhesion molecules expressed by leukocytes and by the endothelium (Figure 1). This multistep process is a cell-to-cell adhesive reaction that involves specific binding of membrane receptors on one cell to counterreceptor structures on the other cell. Several adhesion receptors belonging to different families, including integrins and selectins, have been shown to participate in this mechanism. In the current model, selectins are implicated in the initial rolling, while adhesion receptors from the integrin family and the immunoglobulin superfamily are involved in the firm attachment, flattening and extravasation of leukocytes. Leukocytes

have to adhere to the endothelium before transmigrating, and it is difficult to distinguish between adhesion molecules, involved only in adherence, and proteins involved in the transmigration process. However, several studies have shown that intercellular cell adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), platelet endothelial cell adhesion molecule 1 (PECAM-1) and selectins are important for leukocyte diapedesis between endothelial cells.

Selectins

The selectin family comprises three proteins: E-selectin (CD62E), L-selectin (CD62L) and P-selectin (CD62P). They all contain a lectin domain, an epidermal growth factor domain, and a variable number of short consensus repeats of 60 amino acids present in the complement regulatory proteins. The three selectin genes are located on chromosome 1. E- and P-selectins are expressed on endothelial cells, while L-selectin expression is restricted to leukocytes. Selectins bind to carbohydrate ligands via their lectin domain. It has been shown that tetrasaccharides sialyl Lewis X and sialyl Lewis A have a ligand activity for all the three selectins. The role of selectins in leukocyte transmigration is still debated.

E-Selectin E-Selectin (CD62E) is a 115 kDa glycoprotein, only expressed on endothelial cells after activation by interleukin 1 (IL-1), tumor necrosis factor α (TNF α) or bacterial lipopolysaccharides. After endothelial cell stimulation, newly synthesized E-selectin is rapidly detected, with a maximal surface expression after 3–6 h and a return to basal levels within 24 h. This rapid downregulation, although not completely understood, has been explained by the release of a soluble form of E-selectin, and internalization of the molecule. This regulation of E-selectin expression might be crucial to control leukocyte accumulation in inflammatory responses. Several ligands for E-selectin have been identified on leukocytes, but have not yet been cloned. Monoclonal

Figure 1 Leukocyte extravasation as a multistep process regulated by endothelium.

antibodies (mAbs) specific for E-selectin have been shown to inhibit leukocyte transmigration. It has been suggested that binding of leukocytes to E-selectin on activated endothelium upregulates CD11b (Mac-1) on the leukocytes, and induces an increased adhesion through ICAM-1/Mac-1 interaction.

P-Selectin P-Selectin (CD62P), previously termed PADGEM or GMP-140, is a single chain glycoprotein of 140 kDa expressed in platelets and endothelial cells. In platelets, P-selectin is stored in α granules, whereas in endothelial cells it is found in Weibel-Palade bodies. After activation, P-selectin is mobilized to the external plasma membrane within minutes. This increase in P-selectin expression is transient, and the protein is rapidly internalized inside the cell, where it is degraded or recycled. P-selectin is also upregulated transcriptionally by TNF α . Two ligands have been identified: the P-selectin glycoprotein ligand 1 (PSGL-1), expressed on various leukocytes, and a 120 kDa ligand expressed only on myeloid cells. P-selectin-deficient mice have been shown to be deficient in leukocyte extravasation.

ICAM-1

In general, interaction of leukocytes with ICAM-1 seems to be necessary for their extravasation. ICAM-1 (CD54) is a single-chain membrane glycoprotein of 80–115 kDa, with five immunoglobulin (Ig)-superfamily domains in its extracellular portion. ICAM-1 is moderately expressed on resting endothelial cells, but at sites of inflammation and immune responses the release of cytokines, such as TNF α , IL-1 or interferon γ (IFN γ), results in augmented cellular expression of ICAM-1. The expression of ICAM-1 has also been demonstrated on lymphocytes, monocytes and other nonhematopoietic cells, such as fibroblasts, epithelial cells and mucosal cells. ICAM-1 is a ligand for CD11a/CD18 (LFA-1) and for CD11b/CD18 (Mac-1). The primary binding site for CD11a/CD18 is located in the NH₂-terminal first Ig-like domain of ICAM-1, with domain 2 also involved in this interaction, while the binding site for CD11b/CD18 is in the third Ig-like domain. ICAM-1 also is a receptor for the major group of rhinoviruses and the malaria trophozoite *Plasmodium falciparum*; the binding sites for both ligands, though distinct from the LFA-1 binding site, are located in the first two domains of the ICAM-1 molecule. In addition, ICAM-1 is a receptor for CD43 and hyaluronan. The interaction between Mac-1/LFA-1 (CD11b/CD18) and endothelial ICAM-1 is a well-documented adhesion pathway, important in the adhesion and extravasation of leukocytes. It has

recently been shown that fibrinogen is a ligand for ICAM-1, and that fibrinogen binding to ICAM-1 results in enhanced adhesion of leukocytes to endothelial cell monolayers and an increase in their transendothelial migration. These results suggest that fibrinogen might act as a bridging molecule: for monocyte and polymorphonuclear leukocyte adhesion, it could bind to leukocyte CD-11b/CD18 and to endothelial cell ICAM-1; while for lymphocyte adhesion it could interact with two ICAM-1 molecules on opposing cells. This interaction between fibrinogen and ICAM-1 was inhibited by a commercially available mAb (LB2) specific for the first immunoglobulin domain of ICAM-1, suggesting that this domain is involved in the fibrinogen interaction with ICAM-1. However, the inhibition obtained with LB2 on fibrinogen-dependent adhesion was only partial, even at a high mAb concentration. This limited inhibition might reflect the fact that LB2 is not reacting with the exact binding site of fibrinogen on ICAM-1, but rather to a nearby site. Alternatively, an unidentified fibrinogen receptor present at the surface of endothelial cells could contribute to fibrinogen-mediated adhesion of leukocytes. Both fibrinogen-mediated leukocyte adhesion and transendothelial migration could be inhibited by a peptide from the fibrinogen γ chain.

VCAM-1

VCAM-1 (CD106) is a transmembrane glycoprotein of 110 kDa expressed only on cytokine-activated endothelium. A protein containing six Ig-superfamily domains was initially cloned (6D VCAM-1), but this form arises from alternative splicing of a gene which also encodes a seven Ig-superfamily domain form of VCAM-1 (7D VCAM-1), which is the dominant form on activated endothelium. VCAM-1 is a ligand for $\alpha_4\beta_1$ (VLA-4) and $\alpha_4\beta_7$ integrins. VLA-4 binds VCAM-1 through the first and the fourth Ig-like domain. Using mAbs, several studies have shown that VCAM-1 is involved in the transmigration of monocytes and eosinophils, but its involvement in lymphocyte transendothelial migration needs to be clarified.

PECAM-1

PECAM-1 (CD31) is a 130 kDa glycoprotein expressed on endothelial cells, platelets and some leukocytes. CD31 is constitutively expressed on endothelial cells, and its expression is not increased by cytokines. Molecular cloning studies have shown that CD31 is composed of six extracellular Ig-superfamily domains, a short transmembrane region, and a relatively long cytoplasmic tail of 118 amino acids containing potential sites for post-translational

modifications. Alternative splicing of the cytoplasmic tail can generate multiple CD31 isoforms that may differ in phosphorylation, cytoskeletal association and ligand affinity. CD31 is heavily glycosylated and glycosylation accounts for 40% of the mass of CD31. PECAM-1 appears to be able to interact both with itself in an homophilic interaction and with other molecules in an heterophilic interaction. In endothelial cells, CD31 is localized at intercellular junctions, and plays an important role in adhesion of endothelial cells. Its function might be regulated via phosphorylation of the cytoplasmic domain. PECAM-1 is directly involved in the process of leukocyte diapedesis between endothelial cells, as demonstrated by inhibition studies using PECAM-1-specific mAbs and soluble recombinant PECAM-1. Leukocytes blocked in transmigration by anti-PECAM-1 remained attached to the endothelium, clearly implicating PECAM-1 in diapedesis rather than in adhesion.

Cytokines and vascular endothelium

Endothelial cells and leukocytes interact closely in the activation and expression of immunity as well as in inflammatory reactions and hemostasis. Cytokines are important mediators of this interaction, endothelial cells being both a source and target for the action of polypeptide mediators.

Effects of cytokines on endothelial cells

Cytokines produced by activated lymphoid cells and mononuclear phagocytes elicit a complex spectrum of responses in vascular cells. These can be grouped into distinct sets of functions elicited by different cytokines (Figure 2).

IL-1 and TNF α IL-1 and TNF α induce the expression in endothelial cells of an activation program related to inflammation and thrombosis. The antithrombotic properties of endothelial cells

are profoundly altered by exposure to these inflammatory cytokines, which induce tissue-type procoagulant activity and suppress the cell surface anticoagulant activity mediated by the thrombomodulin–protein C pathway. They also induce the production of platelet-activating factor and augment production of an inhibitor of plasminogen activator, thus inhibiting the dissolution of fibrin polymers.

The production of the arachidonate metabolite prostacyclin (PGI₂) is stimulated by IL-1 and TNF α . Endothelial cell PGI₂ is involved in vasodilatation at sites of inflammation and cell-mediated immunity and in the hypotension associated with systemic administration of these mediators in experimental or therapeutic settings.

Endothelial cells treated with IL-1/TNF α play an active role in the recruitment of leukocytes from the blood compartment. While not directly chemotactic *per se*, IL-1 elicits leukocyte extravasation indirectly by changing the adhesive properties of endothelial cells and inducing production by these cells and tissue elements of leukocyte chemotactic and activating cytokines (CSFs; neutrophil activating protein/IL-8, active on polymorphs; monocyte chemotactic protein 1, active on mononuclear phagocytes).

Interferon γ As in other cell types, IFN γ augments major histocompatibility complex (MHC) class I, and induces MHC class II antigen expression in endothelial cells; it also augments lipopolysaccharide-induced production of IL-1. These changes render endothelial cells able to present antigen to T lymphocytes and thus to act as accessory cells. In the same perspective one can view the slow enhancement of ICAM-1 expression produced by this cytokine: ICAM-1, presumably by facilitating cell-to-cell interaction, can facilitate antigen presentation under conditions of low density of class II MHC. Thus, IFN γ activates a set of properties of endothelial cells related to accessory cell function, without inducing proinflammatory/prothrombotic or proliferative/migratory activities.

Figure 2 Functional programs activated by cytokines in endothelial cells. VPF, vascular permeability factor, also known as vascular endothelial growth factor; FGF, fibroblast growth factor.

Granulocyte and granulocyte-macrophage (GM) colony-stimulating factors (G-CSF, GM-CSF), transforming growth factor β (TGF β) and fibroblast growth factors (FGFs) These cytokines, which regulate growth and differentiation of hematopoietic cells (G-CSF and GM-CSF), mesenchymal cells (FGFs) or both (TGF β), induce proliferation and migration of endothelial cells. The induction of endothelial cell growth by TGF β is only observed in three-dimensional culture systems, with an inhibitory effect when cells are grown in monolayer. Consistent

with these *in vitro* activities, these cytokines induce angiogenesis *in vivo*.

IL-4 and IL-13 IL-4 and IL-13 selectively induce VCAM-1 and inhibit E-selectin and ICAM-1. These cytokines also amplify production of chemokines by endothelial cells. It is likely that these actions of IL-4 are important in the pathogenesis of the late-phase reaction which is associated with allergy.

Cytokines produced by endothelial cells

Endothelial cells produce cytokines that regulate the hematopoietic system, the proliferation and differentiation of T and B cells and the recruitment of leukocytes at sites of inflammation; endothelial cells are important producers of CSFs, including G-CSF, GM-CSF and M-CSF. Since G-CSF and GM-CSF act on endothelial cells themselves (see above), one can speculate on autocrine circuits involving endothelial cells and these cytokines, important for sustaining the hematopoietic microenvironment. Upon exposure to inflammatory stimuli (bacterial lipopolysaccharide, IL-1 and TNF α), endothelial cells produce IL-1 and IL-6. These are pleiotropic cytokines which affect the proliferation and differentiation of T and B cells and hematopoietic precursors and induce hepatocytes to produce acute-phase proteins. Thus by producing IL-1 and, at high levels, IL-6, endothelial cells take part in the regulation of specific immunity and acute phase responses. Finally, endothelial cells have the capacity to produce chemokines (MCP-1, RANTES and IL-8) which activate and induce chemotactic migration of leukocytes.

Overview

Endothelial cells are strategically located at the interface between circulating blood elements and tissues. It is therefore not surprising that these cells play an important active role in immunity, inflammation and hemostasis. Cytokine molecules are used as com-

munication signals in the complex bidirectional interaction between leukocytes and endothelial cells. Endothelial cells represent a source of cytokines and, at the same time, a target for the action of various of these polypeptide mediators. Cytokine-induced endothelial cell responses follow discrete patterns: a program related to inflammation and thrombosis is activated by IL-1 and TNF α , while IFN γ activates accessory cell functions. FGFs, G-CSF and GM-CSF elicit functions related to angiogenesis.

In the complexity of the activation patterns they can express, endothelial cells are reminiscent of mononuclear phagocytes: the long utilized term of 'reticuloendothelial system', although now largely abandoned, reflected the recognition of this similarity and interrelationship.

ENDOTOXIN (LIPOPOLYSACCHARIDE (LPS))

Chris Galanos, Max-Planck Institute for Immunology, Freiburg, Germany

It is more than 100 years ago since it was recognized that the pathophysiological activities manifested during gram-negative infections are caused by components of the bacterial surface. Different observations at that time led to the recognition that the toxic principle present in the bacteria was a

firmly bound thermostable substance that was released after death and lysis of the bacterial cells. Hence the designation endotoxin in order to distinguish it from the heat-labile exotoxins which are released from live bacteria. The term endotoxin was first introduced at the beginning of the twentieth

century, most probably by Richard Pfeiffer, a pupil of Robert Koch.

Chemistry

Chemically, endotoxins are lipopolysaccharides (LPSs). They are macromolecules consisting of two covalently linked parts with contrasting chemical and physical properties: a hydrophilic polysaccharide which is subdivided into the O-polysaccharide and the core oligosaccharide, and a hydrophobic lipid region, the lipid A. Such complete LPSs, containing lipid A, core and O-polysaccharide are designated S (smooth)-form LPSs.

The O-polysaccharide is characterized by a high structural diversity among different bacterial genera and among the different serotypes of one and the same genus. It is built up of repeating oligosaccharide units whose structure and composition vary among the different LPSs and determine the O-serological specificity of the given LPS and of the parent bacterial strain. The core is more conservative in its structure and composition so that the relatively few core types identified so far are common to large groups of bacteria. In *Salmonella* the core is represented by an oligosaccharide containing D-glucose, D-galactose, N-acetyl-D-glucosamine, L-glycero-D-manno-heptose and 3-deoxy-D-manno-2-octulosonic acid (KDO). In addition, phosphate and ethanolamine are present. Lipid A is the most conservative part of the LPS molecule; its structure and composition are very similar among Enterobacteriaceae. In *Salmonella*, lipid A consists of a biphosphorylated disaccharide of D-glucosamine in β -1,6-linkage. The disaccharide carries amide- and ester-linked residues of 3-hydroxymyristic acid, which themselves may be esterified with lauric, myristic and palmitic acid. Other constituents frequently present in lipid A are phosphorylethanolamine and 4-amino-4-deoxy-L-arabinose.

The endotoxic activity of LPS resides in the lipid A part of the molecule, the polysaccharide being devoid of toxic properties. All three regions of the LPS, O-polysaccharide, core and lipid A are immunogenic, eliciting the formation of antibodies specific for structures in the respective region.

The presence of the core and of the O-repeating oligosaccharide units is a structural feature of many LPS of Enterobacteriaceae. In LPSs of other genera, however, the overall architecture of the molecule may vary considerably. The same applies to lipid A, whose structure and composition may be subject to large variations, as in the case of photosynthetic bacteria. Here, due to differences in lipid A structure, the LPSs of many photosynthetic bacteria are non-

toxic and may therefore not be designated as endotoxins.

Mutants have been isolated from many gram-negative bacteria – the so-called rough (R) mutants designated Ra to Re. Owing to biosynthetic defects they synthesize incomplete LPSs, lacking the O-polysaccharide, with the core being present in different degrees of completion. S-form bacteria also synthesize R-form LPS which is present in variable amounts in all S-form LPS preparations.

Isolation and heterogeneity

Two widely used methods for the isolation of S- and R-form LPSs in pure form are the aqueous phenol and the phenol chloroform petroleum ether methods, respectively. LPSs obtained by the latter method are essentially free of the usual contaminants (proteins). Purified LPSs are found to be highly heterogeneous. Analysis by sodium dodecyl sulfate or sodium deoxycholate-polyacrylamide gel electrophoresis results in the resolution of the LPSs in numerous bands in a ladder-like arrangement. This heterogeneity is mainly due to the presence of molecules of varying polysaccharide chain length (e.g. varying number of repeating units); LPSs also exhibit a microheterogeneity resulting from differences in the number of substituents such as phosphate ethanolamine, 4-amino-arabinose and acyl residues in the lipid A.

Biological properties

Endotoxins represent the pyrogens (fever-inducing agents) of gram-negative bacteria, pyrogenicity being probably the first activity of endotoxin recognized. Endotoxins are endowed with a large spectrum of biological activities that may be demonstrated *in vivo* and *in vitro*. Of these, pyrogenicity, leukopenia and leukocytosis, induction of the local, generalized Schwartzman phenomenon, and lethal shock are examples of classical endotoxic activities. A summary of the more important biological activities of endotoxin is given in Table 1.

Although endotoxins are so named after their toxic properties, they also exhibit a spectrum of beneficial activities. They induce nonspecific resistance to different infectious agents and to their own toxic effects. Endotoxins induce mitogenic stimulation and antibody synthesis and secretion in mouse B lymphocytes. The mitogenic activity of endotoxin for mouse B cells may be demonstrated both *in vivo* and *in vitro*. It is interesting that LPS exhibits no mitogenic activity for human or rabbit B lymphocytes *in vitro*.

Table 1 Biological activities of lipopolysaccharides and free lipid A

Pyrogenicity	Induction of nonspecific resistance to infection
Lethal toxicity in mice	Induction of tolerance to endotoxin
Leukopenia	Induction of early refractory state to temperature change
Leukocytosis	Adjuvant activity
Local Schwartzman reaction	Mitogenic activity for cells
Bone marrow necrosis	Tumor necrotic activity
Embryonic bone resorption	Macrophage activation
Complement activation	Induction of colony-stimulating factor
Depression of blood pressure	Induction of immunoglobulin G synthesis in newborn mice
Platelet aggregation	Induction of prostaglandin synthesis
Hageman factor activation	Induction of interferon production
Induction of plasminogen activator	Induction of tumor necrosis factor α and other cytokines
<i>Limulus</i> lysate gelation	Induction of mouse liver pyruvate kinase
Toxicity enhanced by growing tumors	Type C RNA virus release from mouse spleen cells
Toxicity enhanced by BCG, <i>P. acnes</i>	Helper activity for friend spleen focus-forming virus in mice
Toxicity enhanced by gram-negative infection	Inhibition of phosphoenolpyruvate carboxykinase
Toxicity enhanced by adrenalectomy	Hypothermia in mice
Toxicity enhanced by D-galactosamine	
Enhanced dermal reactivity to epinephrine (adrenaline)	

Mechanisms of action

The mechanisms by which endotoxin exerts its toxic activities remained unknown up to the middle of the 1980s. Today it is generally agreed that the biological activities of endotoxin are caused indirectly through the action of endogenous mediators induced after interaction of endotoxin with primary targets. Macrophages are probably the most important targets of endotoxin, playing a central position in the development of endotoxicity. Following interaction with endotoxin, macrophages are activated to produce a number of cytokines, such as tumor necrosis factor α (TNF α) and various interleukins (ILs). TNF α is a primary mediator of the lethal activity of endotoxin. Exogenous TNF α administered into experimental animals induces a lethal shock that is indistinguishable from that induced by endotoxin. In certain experimental models antibodies to TNF α inhibit the development of endotoxin shock.

Susceptibility to endotoxin

Sensitivity towards endotoxin is genetically determined – different animals showing an enormous variation in endotoxin susceptibility. Rabbits, dogs and swine are very sensitive, while mice, rats and guinea pigs are, in comparison, much less sensitive. Humans belong to the most endotoxin-sensitive mammals, an amount of 0.03 μg (per 70 kg body weight) of pure endotoxin administered intravenously sufficing to cause a marked leukopenia after 1 h, which is followed by leukocytosis 3 h later. Higher amounts (e.g.

0.1–0.3 μg per adult individual) elicit marked pyrogenic effects that may be accompanied by shivering, headaches, nausea and vomiting. The lethal amount of endotoxin for normal humans is estimated to be of the order of a few micrograms. Therefore, compared to mice, in which the LD₅₀ is in the range of 200 μg (per 15 g mouse), humans exhibit a several thousand-fold higher sensitivity to endotoxin.

Tolerance and sensitization to endotoxin

Experimental animals receiving minute amounts of endotoxin may become tolerant to a subsequent challenge with pyrogenic or lethal amounts of endotoxin. In humans an initial pyrogenic dose of endotoxin induces tolerance to the pyrogenic effect of subsequent endotoxin challenges carried out within short intervals (less than 10 days).

In contrast, normal sensitivity to endotoxin may be increased by treatment with live or killed gram-negative and -positive bacteria. Examples of these are BCG, *Propionibacterium acnes*, *Coxiella burnetii* and *Salmonella typhimurium*. Interferon γ (IFN γ) is an important mediator of the bacteria-induced sensitization to endotoxin. Sensitization to endotoxin is also induced by parasitic and viral infections. Also, hepatotoxic agents, such as D-galactosamine and α -amanitin, and various chemical agents, including actinomycin D, lead acetate and carbon tetrachloride enhance endotoxin activity. In addition, growing tumors, depletion of cortisone (in mice) by adrenalectomy or acute graft-versus-host reaction will lead to a higher sensitivity towards endotoxin.

LPS-binding proteins

It is interesting that LPS, due to its unique physico-chemical properties, exhibits a high affinity for cells of all kinds with which it interacts, regardless of whether these can be activated by LPS or not. LPS also interacts with various plasma and serum components and also with surfaces of all different kinds (glass, plastic, rubber, etc.).

A number of components of plasma or of cellular origin have been demonstrated to interact more specifically with purified LPS. These include, in addition to specific antibodies, high- and low-density lipoproteins, membrane and soluble CD14, LPS-binding protein, bactericidal permeability-inducing protein and others. The final role of these components for LPS activity, which in some cases has been shown to be inhibitory and in others enhancing, is still under investigation.

ENHANCEMENT, IMMUNOLOGICAL

John W Fabre, The Institute of Child Health, University College London Medical School, London, UK

The spectrum of antigens which any organism regards as self is not a fixed and immutable characteristic, but one which is subject to manipulation. This was first observed in nature by R.D. Owen in 1945, who discovered that cattle twins are life-long hematopoietic chimeras, as a consequence of vascular connections between the twin placentae and the exchange of hematopoietic stem cells *in utero*. This general phenomenon was reproduced experimentally in mice in 1953 by Billingham, Brent and Medawar. These observations stimulated great hopes that potent, antigen-specific approaches to immunosuppression, mimicking self-tolerance, would enable clinical transplantation to proceed on diverse fronts. In the event, contrary to all expectations in the 1950s, clinical transplantation has flourished using nonspecific immunosuppression.

Some definitions

Immunological enhancement, tolerance induction and related terms in transplantation are best brought under the single heading of donor-specific immunosuppression. This can be defined as immunosuppres-

sion which, directly or indirectly, inactivates those clones of lymphocytes responsible for the rejection of the particular graft a recipient receives. It is antigen-specific immunosuppression, and leaves untouched the bulk of the recipient's immune system for the defense against infection and the suppression of some tumors. Its great virtue is safety.

General principles

In recent years, major advances have been made in understanding the immunological mechanisms involved in immune nonreactivity to self, i.e. self-tolerance. Three broad mechanisms to prevent the action of potentially antiself-reactive lymphocyte clones appear possible: destruction (clonal deletion); continued survival but nonreactivity (clonal anergy); and suppression by regulatory T cells (clonal suppression). How these mechanisms relate to those involved in nonreactivity to grafted tissue is not certain. Where hematopoietic chimerism is induced, allowing bone marrow stem cells of donor type to seed the recipient thymus, the mechanisms of non-reactivity might be similar to those of self-tolerance.

However, in most clinically relevant situations, involving adult recipients of solid organ grafts, the predominant mechanism is likely to be that of T cell-mediated suppression.

A variety of additional factors, not applicable in self-tolerance, might also be operating in adult transplant recipients, e.g. altered immunogenicity of the graft, antibody-mediated suppression.

Traditionally, there have been two major approaches to donor-specific immunosuppression in transplantation:

1. *Antigen-induced suppression (active enhancement)* refers to specific immunosuppression induced by treatment of the recipient with preparations containing donor histocompatibility antigens.
2. *Antibody-induced suppression (passive enhancement)* refers to specific immunosuppression induced by treatment of the recipient with antibodies directed at donor histocompatibility antigens.

Over the past few years, there has been renewed interest in the potential of *anti-idiotypic immunity* for regulating immune responses. Very impressive work has been done on the suppression of experimental autoimmune encephalomyelitis (EAE) by immunizing with autologous T cell clones and even synthetic peptides corresponding to T cell receptor variable regions. However, whether or not these ideas can be translated in practice to the more complex area of immunosuppression in clinical transplantation remains to be seen.

The 'induction' and 'maintenance' phases

When considering donor-specific immunosuppression, one usually concentrates on the induction phase, that is, the period around the time of grafting when the recipient is being treated. During this phase, the immunological interactions in the recipient are likely to vary greatly, depending on the particular protocol used for donor-specific suppression. Several weeks or months after grafting, when active treatment has stopped and the graft has reached a more-or-less stable state, one enters the 'maintenance' phase. There is no precise distinction between the induction and maintenance phases, but it is nevertheless a useful concept to bear in mind. During the maintenance phase, the immunological mechanisms involved in graft acceptance are likely to be the same, irrespective of the precise protocols of immunosuppression (whether they be donor specific or nonspecific) used in the induction phase. The

presence of the graft is likely to be the dominant immunoregulatory factor.

Active enhancement

The first example of active enhancement was in fact published in 1906 by S Flexner and JW Jobling. At the turn of the century, there was much interest in the potential of vaccination as a therapeutic procedure. Flexner and Jobling immunized rats with a heat-killed transplantable sarcoma in the expectation that on rechallenge with live tumor the 'vaccination' would protect against tumor growth. However, the tumors in vaccinated rats grew much more rapidly than normally, a result which of course did not fit into any established theoretical framework of that era.

When considering active enhancement, a clear distinction must be drawn between experiments where neonatal animals are treated with donor bone marrow, and those where adult graft recipients are treated with various antigen preparations. In the neonatal situation, the treated animals become hematopoietic chimeras, and such chimerism, even if at low levels, is essential for maintaining the state of non-reactivity towards the donor strain. These experiments are unlikely to be relevant to donor-specific immunosuppression for organ allografts in adult animals, where classical hematopoietic chimerism does not occur.

The first experiments which successfully induced life-long acceptance of allografts in adult animals were performed by F Shapiro and colleagues in 1961. This group used active enhancement to suppress the rejection of skin grafts in mice. Since that time, a huge literature on this subject has been published, involving innumerable permutations and combinations of therapy. What has emerged is that active enhancement can be a very powerful approach to donor-specific immunosuppression. However, it should be remembered that exposure to antigen normally results in sensitization, i.e. a state of specific heightened immune reactivity. The factors regulating suppression versus sensitization following antigen exposure are poorly understood. It is this risk of unpredictable sensitization (leading to more vigorous and rapid graft rejection than normal) which has effectively precluded the clinical application of active enhancement to the present time.

Factors favoring suppression

From the mass of experiments on active enhancement, one can discern certain aspects of protocol which favor the development of specific immuno-

suppression, rather than sensitization. These are as follows:

1. *Route of administration.* The intravenous route is most favorable. In many studies, it has been demonstrated that identical treatments given intravenously and by other routes have resulted in suppression by the intravenous route, and sensitization by other routes (e.g. subcutaneous, intraperitoneal).
2. *Dose of antigen.* In general, the higher the dose of antigen, the more likely it is to induce immunosuppression.
3. *Timing of antigen exposure.* Multiple, closely spaced treatments are most effective. Where single treatments are given, a period of 1–2 weeks before grafting is the most favorable.
4. *Physical state of the antigen.* Donor histocompatibility antigens can be given in many ways, varying from whole living cells through to highly purified, water-soluble molecules. For many years, it was widely believed that genuinely water-soluble histocompatibility antigens would offer potent donor-specific immunosuppression, free from the risk of sensitization. However, it was not possible to test this idea until the recent availability of histocompatibility antigens lacking the hydrophobic transmembrane domain. Such water-soluble molecules are often ineffective for donor-specific suppression.
5. *Concurrent use of nonspecific immunosuppressive agents.* The use of active enhancement in conjunction with agents such as antilymphocyte serum, corticosteroids, azathioprine and cyclosporine has frequently been shown to result in better graft survival than that achieved with either agent alone.

The risk of sensitization

This is most obviously seen when antibodies develop to the histocompatibility antigens used in the active enhancement protocols. If these react with the graft donor, then, in the clinical situation, hyperacute rejection will occur at the time of grafting. Cellular sensitization, in the absence of antibodies, is likely to go unnoticed before grafting, but can give rise to early and vigorous rejection episodes which cannot be controlled by the immunosuppressive drugs currently in use.

Blood transfusions

In the late 1960s and early 1970s, clinical transplantation centers worldwide introduced policies of minimum transfusion, to try to decrease the potential risk of sensitization to histocompatibility antigens. How-

ever, kidney graft rejection in the transplant patients became more severe. In 1973, Opelz and Terasaki reported that random pregraft blood transfusions in fact markedly improved graft survival. By the late 1970s the pendulum had come full swing, and many centers would not transplant patients who had not previously been transfused. In many centers, there are now policies of deliberate blood transfusion, i.e. transfusions given not for anemia, but specifically for their beneficial effect on the survival of a subsequent graft.

The mechanism whereby blood transfusions are effective is unknown, but is likely to involve some form of active enhancement. The fact that the beneficial effect can be obtained from a single, random transfusion from a donor unrelated to the eventual kidney donor raises questions of specificity. However, given the large number of histocompatibility loci now known to exist, the probability that unrelated individuals might share one histocompatibility antigen is not insignificant. Moreover, many histocompatibility antigens have 'public' determinants, i.e. allodeterminants present on the products of many alleles.

Passive enhancement

The use of antibodies to donor histocompatibility antigens to suppress graft rejection was first demonstrated in tumor transplantation studies in the early 1950s. When passive enhancement was tested with skin grafts, its effect was noted to be weak. Graft survival was prolonged by only 2 or 3 days, and the clinical applicability of this approach was not considered of any great interest. However, the development of microsurgical techniques in the 1960s made possible the use of vascularized heart and kidney allografts in studies in inbred rodents. By the late 1960s, French and Batchelor in the UK and FP Stuart and his coworkers in the USA had established that passive enhancement was remarkably successful at suppressing kidney graft rejection in rats. Treatment of graft recipients with one or two injections of anti-donor antiserum at the time of grafting could suppress the rejection response completely, and result in life-long acceptance of major histocompatibility complex (MHC)-incompatible kidney grafts. This caused considerable excitement at the time, and the first attempts to reproduce this phenomenon in the clinic were reported in the early 1970s.

Mechanisms

The mechanisms whereby passive enhancement suppresses rejection is not clear. The most likely possibility is that the antidonor antibodies interact with

the interstitial dendritic cells (passenger leukocytes) of the graft and thereby prevent these highly immunogenic cells from stimulating the host's immune system.

Specificity of the enhancing antibodies

Antibodies to both class I and class II MHC antigens of the donor have been shown to be effective for passive enhancement. However, it is possible that anti-class II antibodies might be more effective.

The importance of the Fc region of enhancing antibody

There are many conflicting reports on the efficacy of the different classes and subclasses of antibody for passive enhancement. Overall, it is likely that immunoglobulin M (IgM) is not very effective and that the complement fixing classes (e.g. IgG2a in the mouse) are most effective. What is clear, however, is that F(ab')₂ fragments of enhancing sera are totally ineffective, and this is an important point to note.

Potency of passive enhancement

The high hopes for passive enhancement stemmed from studies with organ grafts in inbred rats. Even here, however, the efficacy varies markedly in different donor/recipient strain combinations. Several attempts at passive enhancement in larger experimental animals (dogs, primates) have been disappointing. Passive enhancement is clearly a relatively weak form of immunosuppression, but one that could make a contribution as part of a more complex protocol for immunosuppression.

The problem of hyperacute rejection

In humans and most large experimental animals, the presence at the time of grafting of antibodies to donor histocompatibility antigens results in immediate graft destruction ('hyperacute' rejection). This is caused by the interaction of the antibodies with the vascular endothelial cells of the graft, the fixation of complement and the consequent triggering of intravascular blood coagulation and vascular spasm. For reasons which are not entirely clear, this does not occur in most donor-recipient strain combinations studied in the rat. This has allowed passive enhancement to be studied in great detail in inbred rats.

However, the injection of antidonor antibodies in the clinical situation carries the risk of inducing hyperacute rejection. The early clinical studies attempted to overcome this problem by using F(ab')₂ and Fab fragments, because these preparations would not fix complement. However, it later became clear that such fragments are totally without enhancing activity. The use of noncomplement fixing IgG subclasses for passive enhancement is probably the only available option. In fact, noncomplement fixing mouse IgG1 monoclonal antibodies to polymorphic determinants of rat MHC antigens have been shown to be effective for passive enhancement, although large doses of antibody were required.

Future prospects

It has been demonstrated on several occasions that long-surviving patients develop at least an element of donor-specific nonreactivity (e.g. disappearance of cytotoxic T cell precursors against donor antigens). This demonstrates that antigen-specific downregulation of the immune system towards a graft is certainly possible in humans, and that what is required is to achieve this state at the time of grafting. The induction of donor-specific immunosuppression in clinical transplantation is probably the most important goal in transplantation research. When it is achieved, it will mean in essence that immunosuppression will be both safe and effective. This will not only greatly benefit existing clinical transplantation programs, but will broaden the use of transplantation as a therapeutic procedure for the replacement of diseased and defective tissues.

ENZYME LABELING OF ANTIBODIES AND ANTIGENS

Stratis Avrameas and **Thérèse Ternynck**, Department of Immunocytochemistry, Pasteur Institute, Paris, France

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Based on the principle that an antibody reacts reversibly with its corresponding antigen in a highly specific way, several procedures have been developed in which antibodies or antigens labeled with appropriate tracers are used for the localization, detection or quantitation of substances of biological interest. The precursor of this type of procedure, immunofluorescence, based on the use of antibodies conjugated with fluorescein, was employed for the localization of cellular antigens, and was introduced by A Coons and collaborators in 1941. Since then, the techniques based on labeled antibodies or antigens have been diversified and developed. They now represent the most sensitive and widely used techniques. Radioelements, fluorochromes, heavy metals and enzymes, at this moment, constitute the most often used tracers.

Enzymes as tracers were introduced in 1966 by PK Nakane and GB Pierce in the USA and S Avrameas and J Uriel in France. The former group employed antibodies labeled with peroxidase for the immunocytochemical detection of cellular constituents, while antigen labeled with peroxidase or trypsin and antibodies labeled with peroxidase were used by the latter group for the detection of immune precipitates. Enzymes, because of their catalytic nature, offer the possibility of high amplification associated with either simple or sophisticated systems of detection and/or quantitation. This confers to immunoenzymatic procedures a flexibility of adaptation and, consequently, a wide range of applications. Thus at present various immunoenzymatic techniques are available and employed in such different fields as basic research, human and veterinary medicine, agriculture, and food and drug control. Such immunoenzymatic techniques are mainly employed either for the localization of tissue constituents, the detection of small amounts of antigen present in complex biological media, or the measurement of humoral and cellular components.

General principles

The basic principles underlying the various immunoenzymatic procedures are similar, if not identical, to those already developed for the other immunological procedures using labeled antibodies or antigens. In

immunoenzymatic procedures, however, enzyme-labeled antigens are used only occasionally and almost exclusively for the quantitation of small molecular weight substances. In all the other cases, enzyme-labeled antibodies are employed and the steps followed are more or less similar. Thus, as for immunofluorescence, in the enzyme-immunocytochemical localization of a tissue antigen an unlabeled antibody prepared in species A is usually first allowed to react with the cellular preparation. Then, after washings, an antibody, recognizing the immunoglobulins of species A, linked to an enzyme by means of either covalent bonds or biospecific covalent interactions, is added. Finally, after incubation and washings, the sites of enzyme activity are revealed by a cytochemical substrate, specific to the enzyme used as the tracer. Similarly, in order to detect an antigen in a complex biological medium, after an appropriate separation of the various constituents present in this medium, for example by electrophoresis in polyacrylamide gels, the antigen is immobilized on an insoluble phase, such as nitrocellulose or nylon, incubated with a specific unlabeled antibody and then the same sequence of steps, as above, are followed. For the localization or detection of antibodies, similar procedures are used. Thus, to the cellular or otherwise immobilized antibody, the antigen is added, allowed to react, then an enzyme-labeled antibody recognizing the antigen is added and finally the enzyme is revealed by an appropriate substrate.

Even if enzyme immunoassays enabling the quantitation of antigens (or antibodies) present some special features, the basic design and reagents used are similar.

From the above, it appears therefore that antibody, enzyme, and antibody-enzyme linkage are the most important elements of effective and sensitive immunoenzymatic assays.

Enzymes as labels

In principle any enzyme can be used as a label but, in practice these enzymes should express certain characteristics. Since all immunoenzymatic procedures are performed at room temperature, the first requirement is that they be stable under these

conditions. The enzymes used must be the purest possible, i.e. must have a high specific activity and act quickly on their substrate, i.e. have a high turnover number. Furthermore, the procedures used for their detection and/or measurement should be sensitive enough and, preferably, either simple to perform or amenable to automation. Finally, they should not lose a substantial part of their activity after their linkage to the antibodies, and should be available in relatively high amounts.

Horseradish peroxidase and calf intestine alkaline phosphatase, which fulfill more or less all the above conditions, are the enzymes of choice and are the most often used in immunoenzymatic techniques. *Escherichia coli* β -galactosidase and *Aspergillus niger* glucose oxidase are also employed, although to a lesser extent. Occasionally *E. coli* alkaline phosphatase, soy bean urease, bovine liver catalase, *Staphylococcus aureus* penicillinase, and *Electricus eel* acetylcholinesterase are also used.

Depending on the substrates available, these enzymes can be used for the localization (and detection) or the measurement of antigens (antibodies) or both. Localization and detection necessitate the use of specific cytochemical substrates yielding highly colored insoluble products. In contrast, measurement requires the use of specific substrates giving rise to soluble, precisely measurable products. For peroxidase, alkaline phosphatase and glucose oxidase, which enable the localization, detection and measurement of antigens (or antibodies), suitable substrates are available. All the other enzymes, because of the lack of adequate cytochemical substrates, have been found useful only in quantitative immunoassays.

Antibodies

As in all immunologic techniques using labeled compounds, the antibodies employed in immunoenzymatic procedures can be distinguished as unlabeled ones, i.e. those that take part in the first reaction with the antigen, and as enzyme-labeled antibodies that are added secondarily and, usually, in high excess. The sensitivity of these assays depends essentially on the avidity of the first, while their performance depends mainly on the qualities and characteristics of the enzyme-labeled antibody. Since high avidity antibodies are usually present in hyperimmunized animals, when possible it is preferable to use polyclonal and/or monoclonal antibodies derived from such animals. In the great majority of cases, an enzyme-labeled polyclonal antibody preparation recognizing immunoglobulins (usually a mixture of anti- μ , and anti- γ and anti- α), or less frequently a

given antigen, is used. The immunoglobulin G (IgG) fraction or the antibodies specifically isolated from the antiserum are bound to the enzyme. Although good results are obtained with labeled IgG, it is preferable, when possible, to use isolated antibodies; the antigen-specific staining is more intense and the non-specific background is weaker.

Labeling of antibodies with enzymes

Antibodies (or antigens) are labeled with enzymes either by covalent or by biospecific noncovalent linkages. To obtain covalent antibody-enzyme conjugates a number of cross-linking agents have been tried, but only glutaraldehyde, *m*-periodate and maleimide derivatives are currently used. Glutaraldehyde, reacting under mild conditions with the free amino groups of proteins, has been used for the preparation of almost all the enzyme-antibody conjugates applied in immunoenzymatic techniques. Treatment of peroxidase (or other polysaccharidic enzymes) with *m*-periodate results in the generation of active aldehyde groups in the peroxidase molecule which react with the free amino groups of antibodies (or antigens) added subsequently. Treatment of enzymes with maleimide (or pyridyl disulfide) derivatives introduces into these molecules active maleimide groups that react with subsequently added antibody molecules carrying thiol groups. All these coupling procedures give rise to heterogeneous populations of enzyme-antibody conjugates, but under certain experimental conditions homogeneous preparations of conjugates composed of one molecule of peroxidase coupled to one molecule of antibody are obtained using either glutaraldehyde or maleimide derivatives as the cross-linking agent.

Enzymes are also linked to antibodies (or antigens) using a number of specifically interacting systems, but only the antigen-antibody and the avidin (or streptavidin)-biotin systems are currently being used. The procedures based on the antigen-antibody reaction require an antibody recognizing the antigen and a second antibody recognizing the enzyme label, both prepared in species A, as well as an antibody prepared in species B and recognizing the immunoglobulins of species A. In a first step, the antibody is allowed to react with the antigen, then the anti-immunoglobulin antibody is added, followed by the addition of the antienzyme antibody, the enzyme and the substrate. These procedures are based on the principles that: 1) enzyme-antienzyme complexes are always catalytically active; 2) the anti-immunoglobulin antibody, added in excess, reacts with the antigen-bound antibody only by one of its two active sites and thus can operate as acceptor for the antienzyme antibody. These multistep protocols are

somewhat shortened by the prior formation of an enzyme/antienzyme soluble immune complex, the most commonly used being the peroxidase-antiperoxidase (PAP) procedure.

Two procedures are used for linking enzymes to antibodies on the basis of the strong interaction between avidin and biotin (dissociation constant 10^{-15} M). The first requires the preparation of antibodies labeled with biotin and an avidin-enzyme conjugate. Biotinylated antibody is allowed to react with the antigen and this step is followed by addition of enzyme-labeled avidin. In the second method antibodies labeled with biotin, native avidin and enzyme labeled with biotin are used. This protocol involves, in the first step, the interaction of the biotinylated antibody with the antigen; in the second step, the incubation with avidin, followed by the addition of biotin-labeled enzyme and substrate. This technique is based on the principle that avidin possesses four specific binding sites able to create bridges between two proteins labeled with biotin. This assay is somewhat shortened by the prior formation of an avidin-biotinylated-enzyme complex and is often called the ABC procedure. Streptavidin, yielding less background, is being more and more used instead of avidin. Its affinity for biotin is similar to that of avidin.

Localization of tissue antigens by enzyme immunocytochemistry

Specific cytochemical procedures for staining enzymes are available for both light and electron microscopy. At the light microscope level, mainly peroxidase but also alkaline phosphatase and occasionally glucose oxidase are used as labels. Because cytochemical staining procedures for enzymes give rise to reaction products of different colors, enzyme-labeled antibodies can be used for the simultaneous detection of two different cellular constituents. Alternatively, paired staining techniques combining autoradiography or immunofluorescence and immunoenzymatic staining are employed for the detection of two antigens. Detection of antigens by immunoenzymatic and immunofluorescence staining give comparable results both in localization and sensitivity.

At the electron microscope level, peroxidase is almost exclusively used as the label because 1) its cytochemical staining permits precise localization and identification of ultrastructural details, and 2) relatively low molecular weight peroxidase-antibody conjugates penetrate more easily into the interior of fixed cells.

Detection of antigens by enzyme cytochemical staining (immunoblotting type)

Like radiolabeled antibodies, enzyme-labeled antibodies are used for the visualization by means of enzymatic cytochemical staining of immune complexes formed in gels or present on various solid carriers. Enzyme cytochemical staining in immunoblot-type procedures, introduced by Towbin and colleagues in 1979, has been found particularly useful and is currently being used. Such procedures increase considerably (10- to 100-fold over conventional protein staining) the sensitivity of the detection of an immunoprecipitate. All the considerations concerning enzyme-immunocytochemical staining are also applicable to these procedures, but apparently better results are obtained with substrates giving rise to highly contrasting colors ranging from blue to black.

Quantitation of antigens by enzyme immunoassays

A number of procedures can be used for the precise measurement, by enzyme immunoassay, of minute amounts of antigens. Enzyme immunoassays, or in their abbreviated form EIA, are divided into homogeneous and heterogeneous tests. In homogeneous assays there is no need to separate the antigen-antibody immune complexes from free antigen and/or free antibody; however, such a separation is required in heterogeneous assays. The heterogeneous enzyme immunoassays are described in the entry entitled ELISA.

The homogeneous assays are based on antibody-mediated changes in enzyme activity. A specific antibody, by reacting with an antigen-enzyme conjugate, diminishes the capacity of the enzyme to interact with its substrate and, consequently, decreases the enzyme's activity; addition of free antigen proportionally restores the enzyme's activity. Satisfactory results are obtained in these assays only when the antigen is hapten and the enzyme label is either glucose-6-phosphate dehydrogenase or malate dehydrogenase. To date, the most widely used homogeneous enzyme immunoassay, known commercially as EMIT (enzyme-multiplied immunotechnique), is employed, essentially to test drugs. It is rapid and simple. However, its sensitivity is limited and therefore it is applicable only when ligands are present in relatively high concentrations. Several variants of this basic homogeneous enzyme immunoassay employing enzyme inhibitors, prosthetic enzyme groups, enzyme substrates and two enzymes

catalyzing consecutive reactions have been described. Although they are based on original and interesting principles, such procedures are only rarely employed, if at all.

ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA)

Stratis Avrameas and Thérèse Ternynck, Department of Immunology, Institut Pasteur, Paris, France

Yalow and Berson's development in 1959 of the radioimmunoassay based on the use of a new tool, i.e. an antigen labeled with a radioactive tracer, introduced the ability to measure a substance with both accuracy and high specificity. Although radioimmunoassay is highly sensitive and versatile and it has been applied with success in various fields, its further extensive development has been hampered by the inherent drawbacks encountered with radioisotopes. In order to overcome these difficulties, several alternative procedures based on the use of other marker substances, such as free radicals, chemiluminescent or fluorescent labels, bacteriophages and enzymes, were proposed. Among them, enzyme immunoassays, probably because of the high amplifying capacity of the enzyme marker and the relatively simple laboratory equipment they require, have been extensively developed during the past 15 years.

Enzyme immunoassays were first reported in 1971 by S. Avrameas and B. Guilbert in France, E. Engvall and P. Perlmann in Sweden, and B. van Weemen and H. Schuurs in Holland. They were employed for the quantitation of antigens and subsequently for the titration of antibodies. These enzyme immunoassays were based on principles similar to those of radioimmunoassays and, therefore, necessitated the use of an antigen or antibody immobilized on a solid phase, i.e. an immunoadsorbent, to separate the free antigen

or antibody from the antigen–antibody immune complex. These heterogeneous or solid-phase enzyme immunoassays were termed, by Engvall and Perlmann, enzyme-linked immunosorbent assay or ELISA. In 1972 Rubinstein and collaborators introduced enzyme-multiplied immunotechnique (EMIT), a homogeneous enzyme immunoassay, in which the immunological reaction and the measurement of the enzyme were performed in the same liquid medium without an immunoadsorbent.

Principles of heterogeneous enzyme immunoassays

The principles of ELISA, as already mentioned, are similar to those developed for quantitative radioimmunoassays but measurement of enzyme activity replaces radioactivity counting.

To quantify antigens by ELISA, both competitive and noncompetitive procedures are used. The first competitive assay, similar to the conventional radioimmunoassay, consists of incubating the antigen to be measured, a constant amount of the same antigen labeled with an enzyme, and a constant and limited amount of immobilized antibody. After washings, the enzyme activity associated with the solid phase is measured. Because the number of antibody-combining sites is less than the number of epitopes present on the unlabeled and labeled antigen,

competition occurs between them. Since the only variable is the amount of the unlabeled antigen, the enzyme retained by the immobilized antibody is inversely proportional to the amount of antigen to be determined. The second competitive assay, the immunometric procedure, is based on the use of a constant amount of immobilized antigen, and a constant and limited amount of enzyme-labeled antibody. The labeled antibody is first incubated with the antigen to be measured, the immobilized antigen is then added and allowed to incubate and, finally, after washings the enzyme associated with the solid phase is measured. As in the first procedure, the amount of the enzyme bound to the solid phase decreases with increasing concentrations of the antigen to be measured. The 'sandwich' assay is essentially the only noncompetitive procedure used in ELISA for the measurement of antigens. It involves the use of a constant amount of immobilized antibody and an excess of enzyme-labeled antibody possessing the same or similar specificities as the immobilized antibody. The antigen is incubated with the immobilized antibody then, after washings, the enzyme-labeled antibody is added and allowed to incubate and, after washings, the enzyme associated with the solid phase is measured; in this case, the enzyme activity is proportional to the amount of antigen added. When monoclonal antibodies are used this procedure can be shortened by adding simultaneously the antigen and the labeled antibody to the immobilized antibody.

In all the above procedures, under the same experimental conditions, calibration curves are prepared using varying amounts of antigen and, in a given sample, the unknown concentration of this antigen is determined by reference to these curves. The competitive assays are the only procedures enabling the measurement of haptens and other small molecules; the 'sandwich' assay, which requires that at least two epitopes be present on an antigen, cannot be used in such cases. The competitive assays are, however, generally less sensitive than the sandwich assay and more susceptible to variations due to interfering substances present in the samples. Furthermore, the non-competitive procedure is more suitable for routine work.

For the quantitation of antibodies the 'sandwich' noncompetitive procedure is most commonly used. This assay involves the use of a constant amount of immobilized antigen and an excess of enzyme-labeled anti-immunoglobulin antibody. The immobilized antigen is incubated with the antibody to be determined. After washings, the enzyme-labeled anti-immunoglobulin antibody is added, allowed to incubate and, after additional washings, the enzyme as-

sociated with the solid phase is measured. Antibody quantitation by this procedure gives satisfactory results in terms of both sensitivity and reproducibility and, for this reason, it has been applied extensively in various fields. However, because antibodies possess different affinities for a given antigen, unlike antigen measurement, antibody measurement in the strict sense is not possible. The values obtained reflect both the quantity and the affinity of the antibody and have to be considered in terms of titration rather than quantitation.

The heterogeneous enzyme immunoassays, like all immunological procedures, always involve, in addition to the specific antigen-antibody binding, various degrees of nonspecific binding. This ratio appears to be primarily dependent on the solid phase and on the properties of the enzyme conjugates.

Solid phase

Immobilization of antigen or antibody on a solid phase is obtained either by covalent binding or by adsorption through noncovalent interactions. Paper discs but also agarose, cellulose and polyacrylamide particles carrying various active chemical groups have been used for the covalent immobilization of antigens and antibodies. These types of immuno-adsorbent are, however, not often used in ELISA. In principle, covalent binding has the advantages of the irreversible binding of ligands and of the preparation of homogeneous immobilized antigen or antibody solid phases. In fact, when sensitive enzyme immunoassays are employed, both of these advantages do not appear to hold true.

Various supports have been tested for the immobilization of antigen and antibody by physical adsorption. Plastic carriers, such as beads, films, plates and tubes, are the most common and have proved the most successful. Adsorption to such surfaces, principally polystyrene, occurs mainly by hydrophobic interactions. Because antigen or antibody immobilization on plastic surfaces is very simple and plastic carriers are easy to handle, this type of immobilization has led to the development of enzyme immunoassays suitable for large-scale testing. Of these, the procedure making use of microtitration plates, introduced in ELISA by A. Voller and collaborators, has enabled the design of automatic devices which are now routinely used. A few years ago, the major disadvantages of the plastic surfaces were that the adsorbing capacity varied from one batch of plastic to another. In the plates now commercially available, this serious drawback is only occasionally encountered. Recently, active functional groups were introduced on the surface of the plastic and proteins

were covalently bound or proteins were adsorbed on to surfaces made more charged and hydrophilic after radiation treatment. The results obtained thus far are not conclusive as to whether such procedures can advantageously replace simple physical absorption on to an underivatized plastic support.

Enzyme conjugates

Biotin-labeled antibodies (or antigens) followed by enzyme-labeled avidin (or streptavidin) are often used in ELISA. However, in the majority of assays, conjugates prepared by covalently coupling enzymes to antibodies (or antigens) by glutaraldehyde, *m*-periodate or maleimide derivatives are used. All the enzyme-labeled antibody (or antigen) preparations, with the exception of peroxidase conjugates, are composed of a more or less heterogeneous population of conjugates, some of which are of high molecular weight. However, in ELISA procedures that involve no particular steric hindrance problems, high molecular weight conjugates containing a large number of enzyme molecules can be used advantageously, provided they do not enhance nonspecific adsorption.

The enzymes most often used in ELISA are horseradish peroxidase, calf intestine, alkaline phosphatase and *Escherichia coli* β -galactosidase. For peroxidase, several chromogens are employed, yielding various colors that allow its spectrophotometric measurement. The results obtained indicate that *o*-phenylene diamine (giving an orange color) is the chromogen that gives the most sensitive and reliable measurement. The fluorometric assays of peroxidase are neither as sensitive nor as reliable as those using chromogens. Alkaline phosphatase and β -galactosidase are easily and accurately measured spectrophotometrically using, respectively *p*-nitrophenyl phosphate and *o*-nitrophenyl- β -D-galactoside as substrates, while minute amounts of these enzymes are measured by spectrofluorimetry using 4-methylumbelliferylphosphate or 4-methylumbelliferyl- β -D-galactoside as substrates. Several other enzymes, for example, urease, glucose oxidase, acetylcholinesterase, penicillinase and catalase, have been proposed as labels in ELISA but they are rarely used.

Evaluation of several parameters influencing ELISA

In general, in ELISA, nonspecific adsorption can be reduced by including in the medium, during the incubation and washing steps, a nonionic detergent, such as Tween-20, either alone or supplemented with a protein, e.g. bovine serum albumin or gelatin. How-

ever, it must be realized that even under the best defined conditions, there will always be nonspecific adsorption of the enzyme conjugate by the coated solid phase.

The choice of the enzyme label depends essentially on how quickly the results are needed as well as on the number of samples to be examined. When a large number of samples has to be tested simultaneously, it is preferable to use enzymes for which stable substrates are available and therefore allowing reactions of long duration. The substrates of alkaline phosphatase and β -galactosidase are more stable than those used to measure peroxidase. Consequently, peroxidase is not well suited to ELISA requiring reactions of long duration but it is particularly effective in rapid heterogeneous enzyme immunoassays. Comparative assays performed using chromogenic substrates and conjugates of peroxidase, glucose oxidase, alkaline phosphatase and β -galactosidase have shown that, after establishing the optimal conditions, these conjugates had virtually identical sensitivities and were capable of measuring equally small quantities.

Enzymes used as labels can be measured using several highly sensitive procedures. Thus with light emission techniques, peroxidase can be detected at the femtogram level. Using 4-methylumbelliferyl- β -D-galactoside, the fluorogenic substrate of β -galactosidase, 5000 molecules of this enzyme in solution are easily measured. Similarly, alkaline phosphatase can be measured in minute amounts using either fluorogenic substrates or amplifying enzymatic cyclic systems. One would expect therefore that, by using such sensitive procedures for the measurement of enzymes, a considerable increase in sensitivity of ELISA would occur. However, when ELISA using either conventional chromogenic substrates or highly sensitive procedures of detection are first optimized and then compared in a given antigen-antibody system, usually no increase in sensitivity is noted or, sometimes, a maximum 5- to 10-fold increase is achieved. For example, when estradiol is measured by a competitive assay using β -galactosidase-labeled estradiol and either the chromogenic (*o*-nitrophenyl- β -D-galactoside) or the fluorogenic (4-methylumbelliferyl- β -D-galactoside) substrate of this enzyme, the detection limit is the same (100 pg ml⁻¹). However, in order to achieve this result, 18 h of incubation are needed with the chromogenic substrate, while 2 h are sufficient with the fluorogenic one. Thus although the intensity and the rapidity of the enzymatic response is improved by using highly sensitive measurement procedures, the detection limit, i.e. the lowest concentration of antigen (or antibody) that can be measured, remains essentially unchanged.

Therefore, it appears that in ELISA, and probably in all the immunological procedures based on the use of labeled substances, the limiting factor is not the detection or the measurement of the enzyme level. The limiting factor is the binding affinity (avidity) of the antibody which will determine the ultimate sensitivity of the heterogeneous enzyme immunoassays.

EOSINOPHIL CHEMOTACTIC FACTORS

Sabine Krüger-Krasagakes and **Beate M Henz**, Department of Dermatology, Charité and Virchow Klinikum, Humboldt Universität zu Berlin, Berlin, Germany

The discovery of eosinophils by Paul Ehrlich in 1879 and the first description of the process of directed single cell locomotion (chemotaxis) by Wilhelm Pfeiffer in 1884 are closely related in time. Ehrlich also noted increases in blood and tissue eosinophils in a great variety of diseases such as parasitoses, asthma, malignant tumors, vesicular and diverse other dermatoses, and in postinfectious reactions ('the pink dawn of recuperation'), but not in acute bacterial infections.

Efforts to explain the increase of eosinophils in these diseases during the subsequent decades resulted in studies in which a great variety of agents were injected into animals. Substances that induced tissue eosinophilia were sensitized lymphoid tissue, proteins, carbohydrates, synthetic polymers, parasite extracts and histamine. The question as to whether these agents were chemotactic by themselves or only chemotaxogenic, i.e. inducing the production of chemotactic factors after injection into the tissue, could only be resolved with the availability of *in vitro* methods to measure chemotaxis (Boyden chambers) in 1962. The current model for eosinophil accumulation in tissues involves multiple separate steps: eosinopoiesis in the bone marrow, generation and action of chemoattractants, eosinophil adhesion to endothelial cells, and extravasation, tissue eosinophil survival and eosinophil priming and activation.

Source, function and chemical nature of eosinophil chemotactic factors

There are two main sources of eosinophil chemotactic factors: 1) blood and tissue fluid; and 2) a diverse number of cells. The main eosinophil chemotactic factors in the fluid compartment are the complement-derived anaphylatoxins C3a and C5a, and to a lesser extent the latter's cleavage product C5a-desarg (Table 1). Whereas both are highly potent chemotaxins for eosinophils, C5a also activates several other mononuclear cell types. Most eosinophil chemotactic factors derive from resident tissue or from peripheral blood cells. They include different chemical entities such as lipids, peptides and proteins (Table 1).

During initial studies, mast cells and basophils were intensely investigated for the release of eosinophilotactic agents because these cells are considered the main effector cells of allergic reactions. The factors isolated were mostly of low molecular weight and probably represented the eosinophilotactic activities of platelet-activating factor (PAF) and the eicosanoids. The low molecular weight eosinophilotactic activity generated *de novo* from neutrophils was later shown to represent primarily leukotriene B₄ (LTB₄) and related eicosanoids (Table 1). All these factors are also able to attract a number of cell types other than eosinophils.

Table 1 Generally accepted and well-defined eosinophil chemotactic factors and their target cells during *in vitro* chemotaxis

<i>Factor</i>	<i>Chemical nature</i>	<i>Migrating cells</i>
C3a	Peptide	Eosinophils
C5a, C5a-desarg	Peptide	Neutrophils, eosinophils, basophils, monocytes
Eotaxin	Protein	Eosinophils
RANTES	Protein	Eosinophils, basophils, monocytes, memory T cells, mast cells
MCP-3	Protein	Eosinophils, basophils
MCP-2	Protein	Eosinophils, basophils
MIP-1 α	Protein	Eosinophils, monocytes, T cells
IL-8	Protein	Neutrophils, eosinophils, T cells
IL-5	Protein	Eosinophils
LCF	Protein	Eosinophils, monocytes, CD4 ⁺ T cells
5- and 12-HETE	Eicosanoid	Neutrophils, eosinophils
LTB ₄ , 20-OH-LTB ₄ , 5-O-HETE, 5-O-ETE	Eicosanoid	Neutrophils, eosinophils, monocytes, fibroblasts
PAF	Ether phospholipid	Neutrophils, eosinophils, monocytes
N-formyl peptides	Peptide	Neutrophils, eosinophils

Subsequently, lymphocyte products with eosinophilotactic properties could be identified which might participate in recruitment of eosinophils to T cell-dependent hypersensitivity reactions *in vivo*. The T cell-derived lymphocyte chemoattractant factor (LCF) has been shown to stimulate potential migration *in vitro* not only of CD4⁺ lymphocytes and of monocytes, but also of eosinophils. A more selective eosinophil chemotactic factor is interleukin-5 (IL-5).

In older studies, a group of inflammatory mediators, the chemokine superfamily, which specifically regulated chemotaxis of certain leukocyte subgroups, was discovered. While most early reports characterized leukocyte-derived chemokines, it is becoming increasingly apparent that chemokines can be produced by a wide array of tissues. In this regard, the small molecular mass CC chemokines eotaxin, RANTES and monocyte chemotactic protein 3 (MCP-3), and to a lesser extent MCP-2 and macrophage inflammatory protein 1 α (MIP α), represent the most potent eosinophil (but not neutrophil) chemotactic cytokines described so far. Although IL-8, a C-X-C chemokine, has clearly been shown to be a potent neutrophil chemotactic agent, the *in vitro* effect of IL-8 on eosinophil chemotaxis is controversial. The direct IL-8-induced eosinophil chemotaxis, as reported from one laboratory, could only be reproduced by other groups after priming of the cells with IL-5.

Finally, extracts from some parasitic worms have been shown to attract eosinophils *in vitro*. Synthetic analogs of bacterial chemotactic factors, the N-formylated peptides, have only weak eosinophil chemotactic activities. It should be noted that most eosino-

phil chemotactic factors, in addition to inducing migration, also have numerous other important biological functions. With regard to the eosinophils, this includes eosinophil chemokinesis, degranulation or selective secretion, enhanced cytotoxicity and endothelial cell adhesion. IL-5 induces differentiation and proliferation of bone marrow eosinophils, activates eosinophils and promotes their survival.

***In vivo* eosinophil chemotaxis**

For IL-5 and the chemokine eotaxin, convincing evidence of *in vivo* activity as eosinophil chemotactic factors has been provided. Much higher concentrations of IL-5 were, however, required for eosinophil chemotaxis *in vivo* than *in vitro*. Neutralizing antibodies to IL-5 are very effective at inhibiting eosinophil accumulation in blood and tissues in experimental models of allergic inflammation and helminth infection. Furthermore, mice transgenic for IL-5 have extremely high numbers of circulating eosinophils, yet show an otherwise normal phenotype.

There are also interesting data on an *in vivo* synergism between IL-5 and eotaxin. Neither of the substances alone induced eosinophil accumulation after intradermal injection in guinea pigs. Low-dose intravenous IL-5, however, caused a rapid (within 1 h) and dramatic enhancing effect on eosinophil recruitment to sites of intradermal eotaxin injections. Thus, IL-5 acts systemically as a hormone to stimulate the release of a rapidly mobilizable pool of bone marrow eosinophils into the circulation and facilitates the eosinophil recruitment from blood microvessels by locally released eosinophil chemoattractants. This

seems to hold also for other chemoattractants. Subcutaneously injected PAF and LTB₄ mediate eosinophil accumulation only in the presence of an IL-5-induced eosinophilia as well.

An important postulate for a truly eosinophil chemotactic factor is its demonstration in normal and/or pathologically altered tissue. This has so far been achieved for C5a, PAF, eicosanoids, IL-5, IL-8, MIP-1 α , RANTES and eotaxin, although the isolation of these factors has not been restricted to eosinophilic tissue. Although some eosinophil-specific chemoattractants have so far been identified, the mechanism by which eosinophils preferentially migrate into tissues are largely unknown. Extravasation of eosinophils involves a number of cell surface adhesion molecules, predominantly selectins for primary tethering and members of the β_1 - and β_2 -integrin family for firm adhesion and transendothelial migration. There is much evidence that the interaction of VLA-4 ($\alpha_4\beta_1$ -integrin), expressed by eosinophils but not neutrophils, and vascular cell adhesion molecule 1 (VCAM-1) on endothelial cells is a major adhesion pathway allowing selective migration of eosinophils. Blocking VLA-4 *in vivo* has been shown to reduce eosinophil accumulation in some models of allergic inflammation. In addition, antibodies to CD11/CD18 or intercellular adhesion molecule 1 (ICAM-1) (β_2 -integrins) reduced eosinophil accumulation in guinea pig skin. Recent studies have also demonstrated that these adhesion processes can be controlled by chemokines. RANTES, but not MIP-1 α or IL-8, is capable of stimulating eosinophil transendothelial migration via VLA-4/VCAM-dependent mechanisms in cells primed with IL-5.

Modulation of eosinophil chemotaxis

As in all biological systems, stimulating factors of eosinophil chemotaxis can be opposed by down-modulating factors. Such agents can inactivate eosinophilic factors, block their interaction with the cell and its receptor, or interfere with the complex cellular mechanism necessary for locomotion. Mediator antagonists such as antibodies to IL-5, IL-4 and MIP-1 α are very effective at inhibiting eosino-

phil accumulation in experimental models of allergic inflammation.

Among therapeutic drugs, corticosteroids and the immunosuppressant cyclosporine are well known, potent, rapidly acting reducers of blood and tissue eosinophil levels. Sympathomimetics and phosphodiesterase inhibitors have a similar effect. More recently, second-generation histamine H₁-receptor antagonists (cetirizine, ketotifen) have been shown to have both *in vivo* and *in vitro* effects on eosinophil accumulation or migration. This effect is not shared by other H₁-receptor antagonists. Also, leukotriene CysLT₁-receptor antagonists and inhibitors of 5-lipoxygenase effectively suppress eosinophil recruitment in allergic inflammation.

In summary, many questions remain to be resolved in elucidating which factors govern the infiltration of eosinophils into tissue, their interplay with each other and with other factors, and their role in pathologic processes.

EOSINOPHILS

David S Silberstein, Zeneca Pharmaceuticals, Wilmington, Delaware, USA
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Eosinophils are postmitotic leukocytes of the myeloid lineage. They are recognized easily in blood films or tissue sections by their large, regular, eosin-staining cytoplasmic granules and segmented nuclei. Although there are some species-to-species variations in morphology, eosinophils have been detected in every vertebrate that has been studied except the hagfish.

In normal human subjects, numbers of blood eosinophils range from approximately 100 to $700 \mu\text{L}^{-1}$, but can be elevated (in extreme cases by a factor of 100 or more) in association with allergies, asthma, parasitic diseases, chronic inflammation in a variety of tissues, certain neoplasms, use of L-tryptophan dietary supplements, and experimental immunotherapies of cancer or acquired immune deficiency syndrome (AIDS). From the bloodstream, eosinophils enter the margined pool and the tissues, where they exhibit their major impact on the pathophysiology of disease. At the local site of inflammation, eosinophils release toxic substances that may kill or damage infectious organisms and surrounding tissue. Eosinophils are also a major source of immunologic mediators that contribute to the development of the tissue lesion.

Cell structure, biochemistry and activation

The nucleus of the mature eosinophil is segmented, with an average lobe index of approximately 2.1. The cytoplasm of the eosinophil is filled abundantly with secretory granules. The large granules have a central crystalloid body and a surrounding matrix containing cationic proteins that are responsible for the binding of acidic dyes, such as eosin. Small granules can also be observed by electron microscopy. These have many of the same constituent substances as the large granules and may represent a precursor or remnant of the large granule rather than a separate class of granule.

The cytoplasm also contains lipid bodies, glycogen and prominent Golgi bodies, and large amounts of lysophospholipase. This enzyme can form crystals of a characteristic shape (bipyramidal needle), known as Charcot-Leyden crystals, which are occasionally found within the eosinophil and more commonly at the site of inflammation in tissues (Figure 1).

The eosinophil surface membrane displays receptors for immunologically active substances, including

Figure 1 Transmission electron micrograph of normal human blood eosinophil. The characteristic features include a segmented nucleus (N), secretory granules with an electron-dense crystalloid core (arrowheads), a lipid globule (L) and a prominent Golgi apparatus (GA). Magnification $\times 20\,000$. (The figure was kindly provided by Dr Khwaja Siddiqui.)

C3a/C5a, C3b, iC3b, Fc γ (Fc γ RII), Fc ϵ (Fc ϵ RII), Fc α , granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin 3 (IL-3), IL-5, tumor necrosis factor (TNF), and other cytokines, the chemokines RANTES, MIP-1 α , MIP-1 β , MCP-3 and eotaxin, mast cell-derived ECF-A tetrapeptides, and formyl-methionyl peptides. Other surface structures involved in immunologic functions include CD4, IL-2R (gp55), LFA-1 and 3, VLA-4 and HLA-DR antigens.

Stimulation of eosinophils through Fc or complement surface membrane receptors induces the directional release of secretory granule contents, the activation of a respiratory burst and associated release of oxygen metabolites, and the release of pharmacologically active lipid metabolites (Table 1).

Eosinophil secretory granules have a crystalline core composed of major basic protein (MBP), an 11 kDa cationic protein that is toxic to a variety of tissues and microorganisms. The matrix surrounding the core contains the structurally related eosinophil cationic protein (ECP, 18–22 kDa), eosinophil-derived neurotoxin (EDN, 18–19 kDa), the eosinophil peroxidase (EPO), elastase, collagenase, arylsulfatase B, β -glucuronidase, histaminase, phosphatases, phospholipase B and D, catalase, nonspecific esterases, and proteoglycans. The EPO is

Table 1 Functions of activated eosinophils

- *Phagocytosis of immune complexes and certain microorganisms* (e.g. *Escherichia coli*, *Candida albicans*, *Trypanosoma cruzi*)
- *Directional release of secretory granule substances*, including the toxic cationic proteins MBP, ECP, EDN, lysosomal enzymes and EPO
- *Release of toxic oxygen metabolites* including O_2 and H_2O_2 . In the presence of the peroxidase and halide ions, H_2O_2 is converted to hypohalous acid, preferentially HOBr
- *Release of pharmacologically active lipid metabolites*, including minor amounts of leukotriene B_4 , major amounts of leukotriene C_4 and D_4 , 15-HETE (15-hydroxyeicosatetraenoic acid), platelet activating factor, prostaglandins E_1 , E_2 and thromboxane B_2
- *Release of cytokines*, including IL-1, IL-2, IL-5, IL-6, IL-8, TNF and $TGF\alpha$

structurally different from the neutrophil myeloperoxidase and is relatively insensitive to cyanide.

The respiratory burst is associated with increased uptake of glucose and oxygen, hexose monophosphate shunt activity, the oxidation of NADPH, and the reduction of O_2 to O_2^- . O_2^- , in the presence of superoxide dismutase, is converted to H_2O_2 , which is converted to hypohalous acid, preferentially HOBr, in the presence of EPO and halide ions.

Activated eosinophils are important sources of the lipid metabolites leukotrienes C_4 and D_4 (slow reacting substance of anaphylaxis) and platelet activating factor, with a release of 100 ng 10^6 cells or more of each mediator measured in some experiments, quantities substantially greater than those released by mast cells.

Eosinophils are also important sources of multiple cytokine species, including IL-5, which can provide positive feedback on eosinophil development, and transforming growth factor α ($TGF\alpha$), which promotes tumor angiogenesis.

Hematopoiesis

Eosinophil development is predominantly in the bone marrow, but may be found at other sites (e.g. liver or lymphoid tissue) in certain human diseases, and in other mammalian species, particularly in embryos and neonates. The formation of cytoplasmic granules begins in the late myeloblast stage and continues through the myelocyte stage. Segmentation of the nucleus begins with indentation at the myelocyte stage and is complete in the mature bone marrow eosinophil.

Eosinophil development does not take place in experimental animals deprived of T cells, and it is reduced severely in patients with T cell deficiencies,

such as in AIDS. The critical T cell function is the production of the hematopoietic growth factors IL-3, GM-CSF and IL-5. These hematopoietins stimulate the growth and differentiation of distinct eosinophil precursor populations in respective order from most primitive to most differentiated, and it is thought that eosinophil development requires the sequential action of all three factors. IL-5, the eosinophil lineage-specific growth factor, is absolutely required for eosinophil development, and it has been detected in high concentrations in plasma of patients with eosinophilia.

The receptors for IL-3, GM-CSF and IL-5 are heterodimeric, with an α chain that confers ligand specificity and a common β chain that is involved in signal transduction. It is known that occupancy of the IL-5 receptor leads to activation of JAK2 kinase, MAP kinase and STAT5. Thus, these three signal transduction molecules may drive commitment to the eosinophil lineage.

Migration to tissues

Segmented mature eosinophils have a half-life of approximately 13 h in the blood after emergence from the bone marrow. The initial process in the exit from the bloodstream to the tissues is the adherence to the vascular endothelium. E-selectin, CD11b/18 and VLA-4 appear to be the most important adhesion molecules involved in this process, with VLA-4 exhibiting eosinophil versus neutrophil selectivity. This adherence can be enhanced by the presence of certain immunologic mediators, such as TNF, or by the eosinophil-selective chemokines RANTES, MCP-3 and eotaxin. Homing to the tissue site is induced by the chemokines or other chemotactic factors (Table 2).

Eosinophils in disease

Eosinophils are able to phagocytose immune complexes and microorganisms (e.g. *Escherichia coli*, *Candida albicans*, *Trypanosoma cruzi*), but these capabilities are generally not as great as those of other phagocytes. The ability to release toxic substances against nonphagocytosable surfaces is probably of greater importance. By this mechanism, eosinophils are able to kill certain metazoan parasites. There is also some evidence to suggest that eosinophil infiltration of tumors increases patient survival in certain types of cancer (and cures certain experimental cancers in mice).

However, the release of toxic substances has a major damaging effect on surrounding tissues at the site of eosinophil infiltration. The cationic granule substances (Table 1) are highly toxic to cells and

Table 2 Immunologic mediators that regulate eosinophil function

- *Eosinophil hematopoietins* (IL-3, GM-CSF, IL-5) – increased longevity in culture, increased cytotoxic function and leukotriene synthesis, reduced cell density, altered proteoglycan synthesis, processing of ECP to the secretory form. IL-5 is a chemoattractant
- *Tumor necrosis factor* – increased cytotoxic function, respiratory burst activities and adherence to vascular endothelium
- *Eosinophil activating factor* (monokine, 40 kDa) – increased cytotoxic function and leukotriene synthesis, processing of ECP to the secretory form
- *Eosinophil cytotoxicity-enhancing factors* (monokines, 10 kDa and 13 kDa, structurally related to thioredoxin) – increased cytotoxic function and leukotriene synthesis, processing of ECP to secretory form
- *Human interleukin 8* (lymphokine, 41 kDa) – chemotaxis and chemiluminescence
- *IL-1 α and β* – increase or decrease secretion of granule substances, depending on the method of costimulation
- *IL-2* – chemoattractant; administration to humans increases cytotoxic function, reduces cell density and induces processing of ECP to the secretory form
- *IL-4* – suppression of Fc γ R expression and IgG-triggered functions
- *TGF β* – suppression of hematopoiesis, induction of apoptosis
- *DF3 secretory epithelial cell mucin* – suppression of adherence to and triggering by IgG-coated targets
- *C3 β chain* – suppression of antibody-dependent cytotoxic function
- *Chemotactic factors and chemokines* – platelet-activating factor, leukotriene B $_4$, formyl-methionyl peptides, IL-5, IL-8, C3a and 5a, eosinophil chemotactic factor of anaphylaxis (mast cell-derived tetrapeptides), histamine, RANTES, eotaxin, MCP-3

tissues *in vitro*, and are probably responsible for damage that is seen at the site of inflammation *in vivo* (e.g. the desquamation of the tracheal epithelium with bronchial asthma or the progressive endomyocardial fibrosis with the idiopathic hypereosinophilic syndrome). Toxic oxygen metabolites and lysosomal enzymes are also thought to contribute to tissue injury.

Leukotrienes C $_4$ and D $_4$ are extremely potent inducers of smooth muscle contraction and inducers of microvascular leakage. Platelet activating factor is a chemoattractant and activator of several types of inflammatory cell. Thus, local release of these mediators may have diverse and pronounced physiologic effects, including the constriction of airways in bronchial asthma and the accumulation of fluid and inflammatory cells in tissues. The success of leukotriene inhibitors in asthma clinical trials supports the importance of the eosinophil (and the mast cell) in the pathogenesis of the disease.

Regulation of eosinophil function

The regulation of eosinophil functions by immunologic mediators is suggested by two lines of evidence. 1) Eosinophils from patients exhibiting an immune response and eosinophilia have enhanced functions as compared with normal eosinophils. These functions include chemotaxis, cytotoxicity, respiratory burst activities and arachidonic acid metabolism. Eosinophils from these patients also have a slightly increased longevity in culture and a reduced density. 2) *In vitro* treatment of purified eosinophils with defined immunologic mediators can enhance or suppress measurable responses to activating stimuli, increase longevity in culture, and alter cell density (Table 2). Thus, certain mediators can induce phenotypic changes in normal eosinophils similar to those observed in eosinophilic patients.

Of the mediators that are potential *in vivo* regulators of mature eosinophil functions, the best studied are IL-3, GM-CSF and IL-5. Where freshly isolated eosinophils undergo apoptosis within 48 h in culture, appropriate doses of these growth factors extend eosinophil survival to 2 weeks and beyond. Eosinophils cultured in this manner have greatly enhanced cytotoxic function and biosynthetic capabilities. Thus, the hematopoietins that stimulate the development of eosinophils from bone marrow precursors also regulate their postmitotic phenotype. Other mediators also have the potential to enhance or suppress functions of eosinophils (Table 2).

There is substantial evidence for the presence of eosinophil hematopoietins and other regulatory molecules in plasma or tissue samples from human subjects with eosinophilia. One study found that three patients with the idiopathic hypereosinophilia syndrome had very high levels of circulating IL-5. Multiple studies have shown high accumulations of these three hematopoietins in the airways of asthma patients. This information suggests that elevated levels of these regulatory mediators are an underlying cause of eosinophilia-associated diseases. It also suggests that therapy directed at the production of certain immunologic mediators may benefit the patient.

EPITOPES

T Chyau Liang, Department of Biochemistry and Molecular Biology, University of Texas–Houston Medical School, Houston, Texas, USA

An epitope is the part of an antigen that interacts with the antigen-specific receptor or antibody. Strictly speaking, an epitope is determined by the specificity of the clonally distributed receptor to which an antigen binds. However, the part of an antigen that can reproducibly elicit B cell or T cell responses is often referred to as an epitope without reference to the specificity defined by the particular receptor. Epitopes, which are often used interchangeably with antigenic sites or antigenic determinants, can be classified as B cell epitopes or T cell epitopes on the basis of the types of cellular responses they elicit.

B cell epitopes bind to specific receptors, which are membrane-bound immunoglobulins (mIgs), on the surfaces of B cells. These specific interactions lead to a series of events that stimulate the expansion of that particular B cell population. As a result of B cell activation, antibodies with the same binding specificities as those of the B cell receptors are produced. This is often referred to as the humoral immune response. In principle, any soluble molecules that can bind to B cell mIgs are potential B cell antigens. However, the specificities defined by the B cell receptors determine the efficiencies of these potential B cell epitopes.

T cell epitopes interact specifically with MHC (major histocompatibility complex) molecules and T cell receptors (TCRs). Thus, T cell antigenic determinants are defined by the specificities of both MHC and TCRs. MHC molecules (both class I and II) have specific binding sites for short peptide fragments. Protein antigens have to be processed by intracellular proteases before they can bind in the peptide-binding groove on MHC molecules. TCRs are structurally similar to mIgs and antibodies. The complementarity-determining regions (CDR) on TCRs physically contact the peptide–MHC complexes. The tripartite interactions involving peptide, MHC molecule, and TCR result in T cell activation by cytokine-mediated mechanisms. The outcome of T cell activation depends on the types of MHC molecules (hence, the antigen-presenting cells) and the types of T cells involved. Peptides bound to MHC class I molecules (which are found on most nucleated cells) typically interact with TCRs on the surface of CD8⁺ T cells (cytotoxic T cells). These interactions eventually lead to cell killing by the activated and expanded cytotoxic T cells. This process is often referred to as the cellular immune response. Peptides bound to MHC class II molecules, which are found

on antigen-presenting cells such as dendritic cells, B cells and macrophages, interact specifically with TCRs on the surface of CD4⁺ T cells (helper T cells). These interactions result in the activation of helper T cells, which then release cytokines to effect macrophage activation and/or B cell differentiation into antibody-producing plasma cells.

B cell epitopes

B cell epitopes interact directly with mIgs on the surfaces of B cells and no processing of the antigen is required for these interactions. As a result, B cell receptors can bind antigens in their native conformations. This is why antibodies raised against native proteins often recognize 'discontinuous epitopes', antigenic determinants composed of amino acids that are far apart in primary sequences but are in close proximity in the folded structures. By the same token, antibodies raised against denatured proteins or synthetic peptide antigens often recognize 'continuous (sequential) epitopes' and cannot recognize the corresponding proteins in their native conformations.

Antigens that can elicit B cell responses are quite diverse; they can be proteins, lipids, carbohydrates, or small molecules (e.g. arsenate, trinitrophenol). This is in contrast to most T cell epitopes which are usually short peptide fragments. The diverse nature of B cell antigens makes it difficult to predict B cell epitopes *a priori*.

Antigen binding to mIgs on B cells triggers a signaling cascade which leads to B cell activation. The activation of B cells may or may not require the help of T cells. Antigens that require the help of T cells for B cell activation are thymus-dependent (T-dependent) antigens. Antigens that can stimulate B cells without the help of T cells are thymus-independent (T-independent) antigens. The majority of protein antigens are T-dependent, while most of the T-independent antigens are polymeric molecules with repeated antigenic determinants. Examples of T-independent antigens include microbial products such as polysaccharides and polymeric proteins.

T-dependent B cell antigens first bind to mIgs on the surfaces of B cells. After binding, these antigens are internalized by receptor-mediated endocytosis or by nonspecific pinocytosis. While in the cell, these proteins remain in the vesicular compartments and are not mixed with proteins in the cytoplasm. These internalized proteins are processed by lysosomal proteases to liberate peptide fragments which then bind to MHC class II molecules. These peptide-MHC complexes then emerge on the surface of B cells where they interact with specific TCRs on the sur-

faces of T helper cells (CD4⁺ T cells). The MHC-peptide-TCR interactions result in cytokine release from T cells to direct B cell proliferation and maturation. The activated B cells eventually differentiate into plasma cells, which have greatly expanded cytoplasm and extensive endoplasmic reticulum and are wholly devoted to the production of antibodies. The antigenic determinants (B cell epitopes) that are involved in the initial binding to the B cell receptors are not usually the same as the determinants (T cell epitopes) that interact with MHC and TCRs. However, these B cell and T cell epitopes might be localized to overlapping regions on the antigen proteins.

T-independent B cell antigens activate B cells by cross-linking the surface receptors. Without the help of T cells, these B cells do not undergo immunoglobulin gene class switching and the antibodies thus generated are predominantly IgM. In contrast, antibody responses to T-dependent antigens usually mature to contain a greater proportion of IgG with a higher affinity for the antigen.

T cell epitopes

TCRs recognize peptide fragments complexed with MHC molecules (either class I or II). Over the years, several structures of peptide-MHC I complexes have been determined. Peptides bind to the MHC in the peptide-binding groove, which is about 30 Å long and 12 Å wide and is formed by two parallel α -helices, in an extended conformation. These structures have provided insights into how the peptide fragments interact with the MHC molecules, how polymorphism in MHC molecules affects immune responses, and how these complexes might interact with TCRs.

Each individual has only a limited number of different MHC molecules. However, these MHC molecules need to bind a large array of short peptide fragments (octapeptides or nonapeptides for MHC I molecules) with high affinities. Although tight binding usually demands extreme specificity in protein-ligand interactions, MHC molecules solve this apparent dilemma by interacting extensively with the ubiquitous backbone amides and the amino and carboxyl groups on the termini of the peptides. MHC molecules interact with only two amino acid side-chains (usually the second and the ninth amino acids starting from the N-terminus of the peptide fragments) from the bound peptides, leaving most amino acid side-chains available for interaction with TCRs. This simple mechanism of peptide-MHC interactions suggests that it might be possible to predict potential T cell epitopes from protein primary

sequences. Indeed, this has been demonstrated in several cases. This mode of MHC-peptide interaction (i.e. most amino acid side-chains available for TCR recognition) allows the immune system to respond to the vast array of antigens. The mammalian genome encodes around 5×10^7 amino acids in the expressed proteins. These diverse protein sequences require that at least six amino acid side-chains be displayed in a TCR-peptide-MHC complex in order to ensure specificity. This plus the two amino acid side-chains involved in MHC binding suggest that the fact that MHC I molecules have evolved to bind peptide fragments of eight or nine amino acids long might not be accidental.

The structures of TCR-peptide-MHC I complexes have recently been determined by X-ray crystallography. These structures confirm the prediction that the complementary-determining regions of TCRs interact simultaneously with the peptide fragments and MHC molecules in order to achieve the diverse specificities.

Class I and class II MHC molecules have different overall structures and are involved in different subsets of immune responses. Differences between peptide interactions with class I and class II molecules include the following. 1) The peptide-binding grooves of MHC II molecules are open on both ends, whereas those on MHC I are not. As a result, MHC II molecules can accommodate peptide fragments longer than nine amino acids (often around 14 amino acids). 2) Peptides can be bound with MHC I molecules in an arched conformation such that some amino acids are lifted from the floor of the peptide-binding groove. In contrast, peptides bound to MHC II molecules lay flat on the floor of the binding groove. Besides these minor differences, the structural basis for peptide binding to MHC II molecules and for TCR binding to peptide-MHC II complexes are probably similar to those involving MHC I molecules.

Since both MHC I and MHC II molecules bind short fragments of peptides, T cell epitopes are composed of short linear peptide sequences, i.e. are not dependent on native protein conformation. Hence, both native and denatured forms of the same protein should have the same T cell epitopes. The requirement for short peptide fragments demands that protein antigens be proteolytically processed before T cell epitopes are available.

Protein antigens of extracellular origin are internalized by receptor-mediated endocytosis or nonspecific pinocytosis. The internalized antigens remain in vesicular compartments, where they are processed by lysosomal proteases and eventually form complexes with class II MHC molecules. These

peptide-MHC II complexes then activate CD4⁺ T cells. CD4⁺ T cell activation in turn leads to stimulation of the antigen-presenting cells (APCs) such as B cells. In contrast, protein antigens of intracellular origins (such as cytoplasmic proteins and proteins which arise from viral infections) are probably processed by multisubunit proteasomes, although the involvement of other proteolytic machineries cannot be ruled out. The active site structures of proteasomes suggest that these enzymes are capable of cleaving proteins into eight or nine amino acid fragments in a sequence-independent manner, a property consistent with the notion that they are responsible for antigen processing. The processed intracellular antigen fragments then combine with MHC I molecules to effect CD8⁺ T cell activation and cellular immune responses.

EPSTEIN-BARR VIRUS, INFECTION AND IMMUNITY

Martin Rowe, Department of Medicine, University of Wales, College of Medicine, Heath Park, Cardiff, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Epstein-Barr virus (EBV) is an important human pathogen. It is carried by the vast majority of adults as a persistent and largely asymptomatic infection. However, it is the most common causative agent of infectious mononucleosis. It can also induce lymphoproliferative disease in immunosuppressed patients and is implicated in the pathogenesis of various malignant diseases.

Characteristics of EBV and its antigens

EBV is a member of the gamma-herpesvirus family. It is an enveloped virus of about 150–180 nm diameter with an icosahedral nucleocapsid containing a double-stranded DNA viral genome of about 172 000 base pairs. The nucleocapsid is composed of a major 160 kDa nonglycosylated polypeptide and a minor 125 kDa glycoprotein, both of which form part of the viral capsid antigen (VCA) complex. The virus lipoprotein envelope contains at least three virally-encoded glycoproteins, designated the membrane antigen (MA) complex. Two antigenically-related MA glycoproteins, gp340 and gp220, potentiate binding of the virus to a specific cell surface receptor molecule during the infection of target cells. The third MA glycoprotein, gp85, is involved in the fusion of bound virus with the host cell membrane. Following fusion, viral DNA is released into the cell and is transcribed and replicated in the nucleus, where it persists as multiple episomal copies.

The 140 kDa CD3d complement receptor molecule (CD21) is the virus receptor in the human host. CD21 expression is largely restricted to mature B lymphocytes, hence the predominant B cell tropism of EBV. However, the B lymphocyte is not the only cell type that is infectable with EBV, as has long been apparent from the association of EBV with undifferentiated nasopharyngeal carcinoma and other non-B cell malignancies (see below). Infection of primary epithelial cells and of immature thymocytes has been achieved *in vitro*, but these infections were demonstrated with a difficulty that contrasts with the ease and reproducibility with which B cells can be infected. EBV infection of resting B cells results in growth-transformation and the establishment of immortalized lymphoblastoid cell lines (LCLs) in which infection is largely nonproductive and only a

limited number of the viral genes are transcribed. The transformation-associated or so-called 'latent' viral proteins expressed in LCLs comprise six nuclear antigens (EBNAs, for EBV-induced nuclear antigens) and three membrane-associated proteins (LMPs, for Latent membrane proteins), whose functions are summarized in Table 1.

Some LCLs are partially permissive for virus production *in vitro*. In such lines, a minor subpopulation of cells express the BZLF-1 protein (encoded by a gene in the *Bam* *HI* *Z* restriction fragment of EBV, beginning with the first leftward reading frame), which is a transcriptional activator that can trigger a cascade of viral gene expression from more than 80 lytic cycle genes. The lytic cycle antigens were first identified using human sera from EBV-positive individuals which contained antibodies reactive in immunofluorescence with virus-producer cells. Historically, these antigens were classified into groups according to whether their expression was independent of DNA synthesis, i.e. early antigens (EAs), or blocked by inhibitors of DNA synthesis, i.e. late antigens. The EAs were further subdivided into diffuse (EA-D) or restricted (EA-R) components according to their cellular localization and their sensitivity to methanol fixation in immunofluorescence tests. The EA genes encode nonstructural proteins, which include transcriptional activators and enzymes. The late antigens are structural proteins of the EBV nucleocapsid (VCA) and lipoprotein envelope (MA).

Immune responses of the host to EBV infection

Persistent infection in the healthy host

An important feature of EBV shared by all herpesviruses is that following primary infection of the host the virus is carried as a persistent infection for life. More than 90% of all adults in all populations worldwide carry EBV as an asymptomatic infection. Infectious virus can be detected in the throat washings of nearly all healthy carriers. In addition, EBV-positive LCLs can be established spontaneously from cultures of circulating B lymphocytes. The virus is transmitted horizontally via salivary secretions, but current opinion is divided as to the target cell of primary infection. Until recently, dogma held that

Table 1 EBV-encoded proteins expressed in nonproductive infection of normal B cells *in vitro*

Viral gene product (alternative nomenclature) ^a		Functions
EBNA1		Essential for viral plasmid replication, mediated through binding to specific DNA sequences in <i>ori-p</i> . Transcriptional activator
EBNA2		Essential for B cell transformation. It is a transcriptional activator that associates with sequence-specific DNA-binding cellular factors such as RBP-J κ and PU.1. It activates viral gene expression (e.g. LMP1 and LMP2) as well as cellular gene expression (e.g. CD21 and CD23)
EBNA3A	(EBNA3)	Essential for B cell transformation. Binds RBP-J κ and antagonizes EBNA2/RBP-J κ function
EBNA3B	(EBNA4)	Not essential for B cell transformation. Binds RBP-J κ and antagonizes EBNA2/RBP-J κ function
EBNA3C	(EBNA6)	Essential for B cell transformation. Binds DNA and is a probable transcriptional repressor. It can also bind RBP-J κ transcription factor and antagonize EBNA2/RBP-J κ function
EBNA-LP	(EBNA5)	Not essential, but greatly enhances efficiency of B cell transformation. Cooperates with EBNA2 during primary infection of resting B cells to induce the G ₀ -G ₁ transition. There is also evidence that it interacts with Rb tumor-suppressor gene product
LMP1		Essential for B cell transformation, and oncogenic in rodent fibroblast assays. Can regulate cell growth, but its main functions are to enhance cell survival and to alter cell phenotype to increase the antigen-presenting capacity. Pleiotropic effects on cell are mediated in part by activation of the NF- κ B transcription factor
LMP2A	(TP1)	Not essential for B cell transformation, but may act to block switch from the latent state into lytic cycle. Substrate for <i>src</i> family tyrosine kinases, and can modulate transmembrane signal transduction.
LMP2B	(TP2)	Not essential for B cell transformation. LMP2B is an alternatively spliced gene product that is identical to LMP2A except that it lacks the amino-terminus kinase-interacting domains. Its function is unclear, but it may complex with and modulate LMP2A function

^aThere is no agreed standard nomenclature for the EBV-encoded proteins, and two versions are in common usage. Use of the nomenclature in parentheses is perhaps less widespread, being confined mainly to European research groups.

primary infection involved epithelial cells of the oropharynx and that these cells harbored a lytic infection from which a secondary latent infection of trafficking B cells led to virus persistence; in this scenario, persistence occurs in the B lymphoid compartment and subsequent secretion of virus in the oropharynx is postulated to derive from foci of secondarily-infected epithelial cells in lytic cycle. Recent re-examination of the available evidence has led people to question whether epithelial cells are involved at all in normal persistent infection. The alternative postulate argues that primary infection occurs in mucosal lymphocytes; these cells are both the reservoir for latent virus and also have the potential to be activated into lytic cycle, producing the virus particles detected in throat washings.

In both scenarios the site of latency is postulated to be the B lymphocyte. This certainly is supported by experimental evidence. Interestingly, reverse transcription polymerase chain reaction (RT-PCR) analysis of viral DNA expression in peripheral blood lymphocytes showed that both the pattern of latent gene expression (EBNA1 and LMP2 only) and the B cell

surface phenotype (CD23⁻ and CD80⁻) are distinct from that of EBV-transformed LCLs *in vitro*. It is very likely that EBV persists in a nondividing long-lived B cell which is effectively invisible to virus-specific cytotoxic T lymphocyte (CTL) responses, and which is sensitive to normal physiological controls over B cell development.

Figure 1 summarizes the essential aspects of EBV persistence and the immune responses that normally keep the pathogenic potential of the virus in check. While the virus apparently persists in a non-dividing and long-lived B cell in an immunologically silent state, the host mounts potent HLA-restricted CTL responses which are specifically directed against target peptides derived from those EBV latent genes expressed in growth-transformed LCLs, in particular EBNA3A, -3B and -3C. The potency and persistence of this CTL response suggests that reactivation of EBV-infected B cells to lymphoblastoid cells with a broader pattern of latent gene expression is a constant feature of the normal biology of EBV infection *in vivo*. The importance of this cellular immune response in controlling EBV-induced B lympho-

antibodies to VCAs and EA-R. Anti-EBNA responses are delayed by several weeks and may reflect the release of EBNA from latently-infected cells following the development of secondary potent EBV-specific CTL responses.

Of the various humoral responses, only the anti-MA antibodies are protective. Protection probably occurs at two levels: 1) by neutralizing infectious virus; and 2) by mediating antibody-dependent cellular cytotoxicity (ADCC) through binding to MA on the surface of lytically-infected cells.

Immune response of the host in EBV-associated diseases

Infectious mononucleosis Infectious mononucleosis (IM) occurs mainly in affluent Western societies where primary infection with EBV generally occurs at a later age. IM is a self-limiting lymphoproliferative disease that is characterized clinically by fever, sore throat, lymphadenopathy, hepatosplenomegaly and abnormal liver functions. Many of the manifestations in IM are probably a consequence of ineffective cellular immune responses to EBV-induced proliferation of B cells or due to inadvertent tissue damage by autoimmune processes. The majority of atypical lymphocytes in the blood of these patients are T cells, and elevated numbers of suppressor T cells, CTLs and natural killer (NK) cells are present. The cytotoxic response shows a broad specificity that is largely non-HLA-restricted, although a minor population of EBV-specific HLA-restricted CTLs is detectable and this subsequently dominates the cellular immune response as the disease resolves itself.

The serological picture in IM patients is distinct from that seen in asymptomatic primary infection in children. In addition to IgM antibodies to VCA, IM patients also show a transient (2–3 weeks) IgM heterophile antibody response of the Paul–Bunnell type. Furthermore, the IgG antibodies to EA are usually directed to the diffuse (EA-D) components rather than to the EA-R as in silent primary infection. The presence of IgG antibodies to EA-D may correlate with lymph node involvement, which is consistent with the elevated incidence of these antibodies in nasopharyngeal carcinoma, where invasion of draining lymph nodes commonly occurs, and their initial absence in Burkitt's lymphoma, when lymph nodes are not usually involved (see below). Unlike silent primary infection, where IgG antibodies to EA and VCA are transient, these antibodies may remain elevated in IM patients for up to 2 years after the clinical symptoms resolve themselves, which is indicative of increased levels of virus production. The antibody response to the gp340/220 MA components is

delayed, which is consistent with the relatively low virus-neutralizing titers observed in IM sera.

Burkitt's lymphoma Burkitt's lymphoma (BL) is a monoclonal B cell tumor and is the most common childhood tumor in equatorial regions of Africa and Papua New Guinea. In these high-incidence regions, EBV is found in all the tumor cells of at least 96% of BL patients. In addition to EBV, malaria and a specific chromosome translocation are cofactors in the development of BL. The chromosome translocation, which results in deregulated expression of the *c-myc* oncogene, is an essential feature of all BLs and is thought to arise as a rare accident of DNA rearrangements occurring during B cell development. Young children who are at greatest risk for developing BL suffer multiple bouts of clinical malaria each year, and during acute attacks their T cell immunity to EBV is demonstrably impaired. It has been suggested, therefore, that these periods of immunosuppression may lead temporarily to increased EBV-induced B cell proliferation which would increase the chance of chromosome aberrations. Alternatively, or additionally, since the malarial parasite is itself mitogenic, the translocation may arise during malaria-induced hyperproliferation of germinal centers. Whatever the precise mechanism of lymphomagenesis, an important feature of BL is the outgrowth of the tumor in the face of normal EBV-specific cytotoxic T cell responses between bouts of malaria.

Serologically, BL patients show elevated IgG antibody titers to VCA and to EA-R. Antibodies to EA-D frequently appear during late stages of the disease. Total anti-EBNA titers may be normal or elevated, but qualitatively there is a broader response so that antibodies to several of the EBNA in addition to EBNA1 may be detected. This characteristic pattern of antibody responses clearly does not reflect altered antigen load due to the pattern of EBV genome expression in the tumor cells themselves since they express only EBNA1 and none of the other latent or lytic genes, but presumably reflects unusual viral activity in normal, nonmalignant cells.

Lymphomas in immunosuppressed individuals

EBV-positive lymphoproliferative lesions of oligoclonal or monoclonal nature may arise in post-transplant patients undergoing cyclosporine immunosuppressive therapy. In contrast to BL, these lymphoproliferations do not have any consistent chromosome aberrations and their cellular and viral gene expression closely resembles that of cultured LCLs. The implication is that the tumors are primarily virus driven and are a direct consequence of

impaired cell-mediated immunity. Patients with Duncan's syndrome have a congenital defect in the ability to mount an EBV-specific cellular immune response, so that primary infection with EBV results in fatal lymphoproliferative disease driven by the virus. EBV-positive B cell tumors in acquired immune deficiency syndrome (AIDS) patients are usually similar to the lymphomas of post-transplant patients but, interestingly, some AIDS patients do develop classical BL-type tumors.

Nasopharyngeal carcinoma Undifferentiated carcinoma of the nasopharynx (NPC) is particularly common in Chinese populations in South-East Asia, where it accounts for nearly 20% of all malignant neoplasms. EBV is present in the tumor cells of all NPC patients, but the etiology of the disease is poorly understood. Genetic, dietary and environmental factors have all been implicated as cofactors along with EBV. Viral gene expression in the tumors is restricted to EBNA1 with or without LMP1 and LMP2. The CTL response to EBV-infected B cells is only marginally reduced in NPC patients relative to healthy controls.

A remarkable feature of the humoral response to EBV in NPC is the characteristic IgA response to lytic cycle antigens. Screening at-risk populations for serum IgA responses to VCA and EA allows the detection of early stages of NPC, at which point the tumor is particularly responsive to radiotherapy. Following eradication of the tumor, the IgA responses diminish and are therefore of prognostic value. IgG responses both to lytic cycle antigens and to the latent antigens are also elevated in NPC. As with BL, the characteristic pattern of antibody responses in NPC is not simply a consequence of antigen load due to viral gene expression in the tumor cells themselves, but must reflect other aspects of virus activity in these patients.

Other diseases associated with EBV EBV has been implicated in the pathogenesis of a number of other diseases, including: oral 'hairy' leukoplakia in AIDS patients, smooth muscle tumors in immunocompromised children, certain T cell lymphomas, Hodgkins disease, central nervous system lymphomas and Sjögrens syndrome.

Evasive strategies by the virus

In common with other persistent viruses, EBV has evolved strategies for evading immune responses so that it is never completely eliminated from the infected host. The hypotheses of EBV latency in healthy carriers have been greatly influenced by studies on EBV-positive BL tumors which are refractory to

CTL lysis. The primary mechanism of immune escape by these tumors is that expression of the immunodominant target antigens (EBNA3A, -3B and -3C) is repressed; EBNA1 is the only virally-encoded protein expressed in BL tumors, and this protein has a unique strategy for evading CTL responses. EBNA1 contains a large glycine/alanine-rich region that somehow prevents processing of EBNA1 target peptides for CTL recognition, but does not affect the ability of target peptides to be presented from other antigens in the same cell. In addition to the restricted pattern of viral gene expression, BL cells are also inherently impaired in endogenous antigen-presenting capability, owing to transcriptional downregulation of the TAP peptide transporter proteins and major histocompatibility complex (MHC) class I products. Finally, these tumors express low levels of cellular adhesion molecules that are involved in CTL:target cell interactions.

It has long been thought that the immune-evasion strategies of BL may not be unique to the malignant cells, but might also be a feature of virus latency in normal healthy carriers. In certain respects this hypothesis is supported by recent research. Thus, in healthy carriers RT-PCR analysis of circulating lymphocytes suggests that EBNA1 and LMP2 are the only virally-encoded proteins expressed. The detection of LMP2 is unexpected, and does pose a problem as LMP2 is a membrane protein that can provide HLA-A2-binding peptides that are transported to HLA in the endoplasmic reticulum in a TAP-independent manner, and CTL recognition of TAP-negative and LMP2-positive target cells has been demonstrated *in vitro*. However, there are several points that should be borne in mind. Firstly, the RT-PCR analysis does not reveal whether all the EBV-positive cells express LMP2, and neither does it indicate the level of expression. Secondly, LMP2 appears not to be an immunodominant target antigen for EBV-specific CTL. Thirdly, it may be relevant the latent EBV-carrying cells *in vivo* lack expression of the CD80 costimulatory molecule.

Given the potent transforming capacity of EBV, it is very important that strategies for immune evasion are balanced by mechanisms for eliminating excessive lymphoproliferation. In this respect it is notable that the LMP1 gene, whose expression is essential for EBV-induced growth transformation of resting B cells, has a major effect upon the immunogenicity of the target cell by upregulating TAP, HLA and cell surface accessory molecules. This ensures that EBV-induced proliferation of normal B cells is accompanied by a concomitant sensitization to cellular immune responses.

Antiviral treatment

The best documented antiviral reagent used to combat EBV is acyclovir, which inhibits the viral DNA polymerase but which has no effect on the latent viral genome. Acyclovir has been used successfully to treat the oral 'hairy' leukoplakia lesions in AIDS patients. However, trials with IM patients showed that, while detectable virus secretion in the oropharynx is abolished by acyclovir treatment, the numbers of latently-infected B cells in the circulation apparently remains unchanged. Most importantly, acyclovir treatment has no effect on the clinical course of IM. The use of interferon α in renal allograft recipients appears to have some effect upon virus secretion, but the effect is less marked than with acyclovir and is similarly ineffective clinically.

The development of a vaccine for EBV has so far concentrated on gp340 MA, either as purified glycoprotein or in recombinant adeno- or vaccinia viruses, with the aim of generating antibodies that are virus neutralizing and which might also be effective against cells in late lytic cycle. Animal trials using the cotton-top tamarin have been encouraging, although the mechanism of protection is unclear, as virus neutralizing antibodies are not always produced in vaccinated animals. Human trials with this vaccine are in progress. An alternative vaccine strategy involves the use of CTL epitope peptides directed against latently-infected cells. A 9-mer peptide, FLRGRAYGL, that is the immunodominant epitope of EBNA3A presented through HLA-B8, is currently being investigated.

Adoptive transfer of EBV-specific CTLs represents an alternative approach to restoring cellular immunity in immunosuppressed patients and may prove useful for the eradication of EBV-positive tumor cells. Rooney and colleagues have applied this strategy in bone marrow transplant recipients, where CTL infusions have reduced the viral load in patients

showing signs of EBV reactivation and resolved an immunoblastic lymphoma.

ERYTHROCYTES

Gian Luigi Castoldi, Hematology Section, Department of Biomedical Sciences, University of Ferrara, Italy

Laura del Senno, Department of Biochemistry and Molecular Biology, University of Ferrara, Italy

Structure and shape of erythrocytes

The final stage of erythroid maturation is the circulating erythrocyte which performs the basic function of oxygen delivery. Normal human erythrocytes

appear as circular, flexible, biconcave discs, lacking a nucleus and most of the cytoplasmic organelles accompanying the erythroid precursors during their differentiation and maturation processes. These cells stain red-orange with a relatively pale centre in normally prepared smears (Giemsa staining), while they

show the characteristic biconcave shape (discocyte) by scanning electron microscopy (SEM).

Resting cells have a diameter of 7.5–8.3 μm . They are 1.7 μm thick (0.6 μm on dried blood films) and have an average volume of 83 μm^3 . When first formed and released from the bone marrow, the young erythrocyte is subjected to some surface remodeling, due to numerous events (mechanical fragmentation, immunologic reactions, chemical alterations) which may irreversibly alter the membrane structure. The progressive loss of membrane fragments, with subsequent reduction of the cell surface area, leads to the formation of a rigid spherocyte, unable to withstand continuous deformations required by circulatory stresses. The maintenance of the normal shape of the erythrocytes is dependent not only on the environment of the cell but also on its metabolic condition and age. Thus modification of the cellular shape appears as a dynamic process which allows the red cell to be stretched (up to one-twentieth of the cell diameter) when passing through circulatory obstructions or narrowed vessels, and to undergo, under physiologic conditions, different reversible changes.

The availability of three-dimensional morphologic features obtained by SEM has provided a careful analysis of a spectrum of red cell shape changes occurring in normal and pathologic conditions. A visual demonstration of the deformation processes of the red cells and of the mechanisms underlying the fragmentation and resealing of these membranes has been obtained from several human and experimental models. Under physiologic conditions the discocyte may undergo two distinct reversible changes, i.e. the *echinocytic* (spiculated) and the *stomatocytic* (cup-shaped) forms, which are strictly dependent on the pH of the medium and intrinsic metabolic rate of the cells. According to Bessis, these two basic features can be viewed as opposite phenomena, resulting from the exposure of the red cells to conditions or substances which are antagonistically active (Figure 1). The persistence of the action of transforming

agents is associated with a progressive deformation of these configurations, leading through morphologically recognizable stages (spheroechinocyte and spherostomatocyte) to a fully developed spherocytic appearance which is a nonreversible condition. Spherocytes are easily trapped by reticuloendothelial cells, mainly in the spleen. The mechanism of the reversible changes is possibly due to the differential expansion of either the outer or inner leaflet of the lipid bilayer. The expansion of the outer half is associated with membrane spiculation, whereas the expansion of the inner half leads to membrane invagination and cup-shaped cells.

Beside these physiologic (reversible) modifications of the red cell shape, some cleavage processes of the membrane or metabolic events may cause a persistent (irreversible) deformation of the cell surface. The variety of the morphologic features of distorted erythrocytes has led to a classification (according to an international Greek nomenclature), which reflects the prominent characteristics of the pathologic cells. The detection of these features offers a key for the interpretation of some underlying disorders in many patients (for example, the presence of acanthocytes in abetalipoproteinemia in liver alcoholic cirrhosis, of codocytes (target cells) in thalassemia, hemoglobinopathies or in hereditary lecithin-cholesterol acyltransferase (LCAT) deficiency, of keratocytes (helmet cells) and schizocytes in microangiopathic hemolytic anemia and disease associated with intravascular deposition of fibrin, of dacryocytes (tear drop cells) in myelofibrosis, of drepanocytes in sickle cell anemia.

Red cell membrane

Several functions of the red cells are closely related to different structures of the cell membrane. These structures are involved in most of the metabolic, antigenic, transporting and receptor activities of the erythrocytes.

Biochemical aspects

The red cell membrane is constituted by a *lipid bilayer* and by a submembraneous network of polypeptides (*membrane skeleton*) which confers upon the red cells the capacity to maintain its characteristic biconcave shape and the flexibility to change shape during passage through the circulation without apparent damage.

Lipids represent 50% of the membrane weight (Table 1). They are asymmetrically distributed across the bilayer plane as well as within each bilayer. This asymmetry is due to the action of an aminophospholipid translocase or 'flippase', possibly related to the

Figure 1 Echinocytic (A) and stomatocytic (C) cells represent distinct morphologic changes of the normal erythrocyte (discocyte) (B), possibly related to the selective expansion of the outer or inner leaflets of the lipid bilayer.

Table 1 Lipid composition of normal human red cell membrane

	Weight (%)	Approx. no molecules/ghost (million)	Outer half of bilayer (%)	Inner half of bilayer (%)
Phospholipids	62	250	~45	~55
Cholesterol	28.9	195	50	50
Glycolipids	6.6	10	100	0
Free fatty acids	2.2	20	?	?

multidrug resistance (*mdr*) gene product. Furthermore, surface-bound membrane proteins may contribute to the nonrandom topography of the lipid plane, leading to the so-called 'cis asymmetry'.

The red cell membrane contains 10–15 major polypeptides conventionally classified as 'integral' or 'peripheral' on the basis of their localization with respect to the lipid bilayer. They are usually identified by their mobility in SDS-PAGE (Figure 2). Most of the biochemical characteristics of these components and their functional properties are summarized in Table 2, see p. 838.

Many of these molecules interact with each other, participating in the building of the membrane *skeleton*, a network of proteins underlying the lipid bilayer membrane, which preserves the structural integrity and deformability of the human erythrocyte – both essential for its survival. This skeleton is a polygonal lattice created by the cross-linking of short *actin* filaments by long tetramers of *spectrin* (25–30% of membrane total protein), which maintains the cellular shape, regulates the lateral mobility and provides structural support for the lipid bilayer. Spectrin is composed of two polypeptide chains, α and β , that are associated in an antiparallel manner into fiber-like flexible heterodimers, approximately 100 nm long. Heterodimers associate head-to-head to form tetramers. The tails of tetramers interact at junctional complexes through the binding to F-actin filaments, leading to a polygonal array mostly composed of hexagons and pentagons. This last interaction is greatly strengthened by protein 4.1. The spectrin–actin–4.1 junction contains other associated proteins, *dematin*, the two polypeptides of *adducin*, *tropomyosin*, *tropomodulin*, that modify and regulate the interaction of the three core components. Protein 4.1 cross-links spectrin dimers with actin and with proteins in the overlying lipid bilayer.

The membrane skeleton is also connected to the integral proteins of the overlying lipid bilayer by *ankyrin* (Figure 2B). This molecule binds β spectrin near the self-association site and links it to the cytoplasmic portion of *band 3* (anion exchange protein 1, AE-1), which constitutes the major integral protein of the red cell, and represents the true anchor

for the membrane skeleton. *Pallidin* is a 77 kDa myristylated peripheral membrane protein that binds to band 3 and probably to ankyrin.

Glycophorins represent a complex family of integral membrane sialoglycoproteins. The obvious function of glycophorins is to provide a negative surface charge that red cells require to avoid cellular adhesion. In addition, they may participate in the transmembrane signalling and bear receptors for *Plasmodium falciparum*.

All the major erythrocyte proteins are affected by one or several types of post-translational modifications, such as proteolysis, oxidation, phosphorylation and fatty acid acylation, which may have profound effects on the function of the protein. Some membrane proteins use a lipid-containing anchor to be inserted in the membrane, just as do most non-glycoprotein membrane-bound polysaccharides. The anchor consists of a complex including phosphatidylinositol (GPI) or a glycolipid. The absence of GPI-linked proteins in paroxysmal nocturnal hemoglobinuria (PNH) is the result of a defect in the very early steps of the biosynthesis of the anchor. The PNH gene resides on the X chromosome.

Several forms of hereditary hemolytic anemias may exhibit some abnormalities in the interaction of the skeletal components. Molecular defects of spectrin and of protein 4.1 have been recognized in some patients with spherocytosis and elliptocytosis.

Antigenic aspects

Immunologic properties of the red cells are mainly related to the presence on their membrane of blood group antigen-bearing molecules (glycoproteins and glycosphingolipids) (Table 3, see p. 840). The most abundant sialoglycoproteins, glycophorin A (GPA) and GPB are integral membrane proteins, which, like band 3 glycoprotein, may extend beyond the surface of the cells with attachment of numerous carbohydrate chains. The external domain of GPA carries blood group M or N activity (depending on the amino acid residues at positions 1 and 5), while GPB carries blood group N activity as well as blood S or s antigen activity with respect to the amino acid substitutions at residue 29. GPC contains the Gerbich

Figure 2 (A) Model of the human erythrocyte membrane showing the major membrane proteins, numbered according to their sequence in SDS-PAGE pattern after Coomassie blue staining (inset). 1–2: Spectrin; 3: band 3 protein(s); 4.1 and 4.2: band 4.1 protein and band 4.2 protein; 5: actin; 6: glyceraldehyde-3-phosphate dehydrogenase; 7: band 7 protein. Red cell membrane sialoglycoproteins (glycophorins), after separation by SDS-gel electrophoresis and staining with the periodic acid–Schiff base stain (PAS), appear to be associated with different ‘PAS regions’. The dimer of glycophorin A is associated with PAS 1 region and migrates within band 3. PAS 2 region is composed of three bands: the monomer of glycophorin A, the dimer of glycophorin B and glycophorin C. The monomer of glycophorin B is associated with PAS 3 region (not shown in the figure). (Adapted from Castoldi and Beutler (1988).) (B) Protein interactions at junctional complexes showing the associations between a spectrin tetramer and band 3, and between spectrin tail ends and GPC in the erythrocyte membrane.

blood group antigens. GPC binds protein 4.1, participating in the anchoring of the skeleton to the membrane. GPD is a shortened form of GPC arisen from an alternative initiation codon on the same RNA. Another member designated glycophorin E (GPE) has been identified in the course of molecular genetic studies.

Band 3 protein carries I, i, H, A and B specificities: the complexity of the carbohydrate chains is variable, as suggested by the fetal (linear) form of the i antigen and the adult (branched) form of the lactosaminoglycan of the I antigen. Furthermore a part of band 3 protein has been possibly associated with the major Rh determinant(s).

Rh polypeptides have been found to be a major fatty acylated membrane protein in red blood cells. The RH locus is composed of two homologous, closely linked genes per haploid genome, one encoding the D protein, the other encoding the CcEe protein(s). Most of the Rh polypeptide chain is hydrophobic and is predicted to reside between the leaflets of the phospholipid bilayer with 12 or 13 bilayer-spanning domains, while the short N-terminus and C-terminus are located intracellularly. They seem to be required for the correct transport or cell surface expression of certain glycoproteins. The absence of Rh antigens may lead to the loss of membrane phospholipid asymmetry and to the appearance of morphologic abnormalities.

An integral 93 kDa glycoprotein, structurally similar to zinc-neutral endopeptidases and related to McLeod antigens, identifies the Kell (K) group, while a 35–43 kDa glycoprotein, the carrier of the Duffy blood group Fy antigen, is involved in the invasion of red cells by *Plasmodium vivax*.

Some antigens are not synthesized by the erythroid cells, but they may be in some way acquired from the plasma, like the glycoproteins Chido (Ch) and Rogers (Rg). Ch and Rg substances are located on the C4d fragment of complement and are acquired by red cells as a consequence of complement activation *in vivo* with subsequent cellular attachment of C4d.

Blood group antigen deficiencies may be associated with some abnormal red cell shapes; for example, the absence of Gerbich blood group antigen(s) is, in some instances, associated with ellipsocytosis (Leach phenotype), Rh null phenotype with stomatocytosis, and McLeod phenotype with acanthocytosis. These features may support the contention that molecules bearing the antigenic determinants are important for maintaining the membrane properties and physiologic functions of the red cells.

Enzyme activities and energy metabolism

The metabolic activity of the red cells and fulfillment of their different functions is dependent on the utilization of glucose in the plasma as an almost exclusive source of energy. Glucose transfer into red cells is accomplished by a membrane carrier which combines with D-isomers of hexose (not fructose) without requiring insulin. The further steps of utilization of glucose involve two major metabolic pathways: the Embden–Meyerhof direct glycolytic pathway (by which the glucose is anaerobically catabolized to pyruvate or lactate) and the hexose monophosphate (HMP) shunt involving a direct oxidative pathway. While the erythrocytes utilize the anaerobic pathway for generating ATP, the HMP does not generate high-energy phosphate bonds. The latter provides NADPH which works as a substrate for the reduction of glutathione-containing disulfides in the erythrocytes, in response to oxidant stress.

A large number of enzymes of glucose metabolism are involved in these processes; however, some enzymatic activities may utilize other substrates (adenosine, inosine, fructose, mannose, galactose, dihydroxyacetone, lactate) different from glucose. These alternative energy sources of the red cells may be important during blood storage.

Red cells are endowed with a further series of enzymes such as carbonic anhydrase (which is considered an early marker of erythroid differentiation), catalase, acetylcholinesterase, aldehyde dehydrogenase, protein kinase activities and dipeptidases.

Ion pump and channels

The osmotic imbalance created by the presence of impermeant polyanions (hemoglobin, 2,3-diphosphoglycerate, glutathione) in the red cells requires a series of regulatory mechanisms, involving the control of small ions, in order to avoid cell swelling and subsequent hemolysis. The membrane of the red cell is easily permeable by plasma water and anions such as chloride (Cl^-) and bicarbonate (HCO_3^-), while cations such as Na^+ and K^+ have a very slow exchange through the membrane. Thus several transporting systems, which are responsible for maintaining a steady-state cation concentration, are constantly needed by the erythrocytes. One of the most important is represented by the Na^+ pump (Na^+/K^+ -ATPase complex) which utilizes ATP for exchanging Na^+ (3 mmol of Na^+ extruded for each 2 mmol of K^+ transported into the cell). Several hormones, such as aldosterone, thyroid hormone and insulin, appear to modulate the activity of the Na^+ pump. Furthermore, various derangements of the red cell Na^+ and K^+ transport pathway have been detected in hyper-

ACHE, acetylcholinesterase; AQP1, aquaporin 1, water transporter; FUT, fucosyltransferase; DAF, complement regulatory molecule-decay accelerating factor; CRI, C3b/C4b receptors.

tensive patients. Ca^{2+} fluxes in the red cells are regulated by another transport system constituted by an enzyme stimulated by calmodulin which improves its affinity for Ca^{2+} . Increase of Ca^{2+} sharply impairs the deformability of the erythrocyte. The Ca^{2+} pump activity appears to be influenced by thyroid hormone.

Band 3 is the conduit for the important chloride–bicarbonate exchange, but it is also the major binding site for a variety of enzymes. The 40 kDa N-terminal cytoplasmic domain binds and inhibits the glycolytic enzymes glucose-3-phosphate dehydrogenase (G3PDH), phosphoglycerate kinase (PGK), aldolase, and hemoglobin too, and modulates the binding of band 3 to protein 4.1, pallidin and ankyrin. The 52 kDa transmembrane domain is composed of 12 or 14 transmembrane helices which form the transport channel. The 1.2 million channels in each red cell can exchange 10^{10} – 10^{11} HCO_3^- and Cl^- anions s^{-1} . An anion moves by a ‘ping-pong’ mechanism in which an intracellular anion enters the transport channel and is translocated outward and released (outward conformation) until the penetration of the channel by an extracellular anion triggers the reverse cycle. The mechanism involves fairly large conformational changes.

Receptors

The red cell membrane is provided with several receptor activities. Some of them include receptors for hormones like insulin (not utilized for glucose transport) or thyroid hormones. In addition β -adrenergic receptors (possibly playing a role in the transport of Mg^{2+}) and acetylcholine receptors have been demonstrated. Erythrocytes bear a complement receptor (CR1) which is able to bind C4b molecules attached to the red cell membrane during complement activation. No transferrin receptors have been detected on the mature erythrocytes, these structures being lost at the reticulocyte stage. Putative receptors for prostaglandin E, parathyroid hormone, diphtheria toxin, ceruloplasmin and opiates have been reported.

Red cell aging and destruction

The average life span of circulating erythrocytes is about 120 days. Aging of the red cells is associated with a decrease of the enzymatic activities, a progressive increase of hemoglobin concentration and red cell viscosity due to loss of total cation and water content (‘dense red cells’), and structural modifications of the membrane with a reduction of the sur-

face:volume ratio, leading to the formation of a rigid spherocyte with enhanced osmotic fragility. These aspects occur in physiologic conditions, but similar features may be observed in various pathologic disorders associated with hemolytic processes.

Trapping of the senescent erythrocytes by reticulo-endothelial cells is the last event of the life of these cells. This phenomenon may be viewed as an immunologic process characterized by the exposure of hidden antigenic sites followed by the binding of naturally occurring autologous antibodies (immunoglobulin G) which trigger the phagocytosis. Exposure of epitopes of band 3 may represent one of the events closely associated with the senescence of the erythrocytes.

Several other damaging processes (oxidative, proteolytic) may intervene during the life of the circulating erythrocytes; some of these are operative concomitantly with the presence of molecular defects of the cytoskeleton or of the hemoglobin structure, accelerating the red cell clearance.

ESCHERICHIA COLI, INFECTION AND IMMUNITY

Rodney D Berg, Department of Microbiology and Immunology, Louisiana State University Medical School-Shreveport, Shreveport, Louisiana, USA

Characteristics of the organism and its antigens

Escherichia coli is a gram-negative, facultatively anaerobic, small bacillus (1–2 µm) in the family Enterobacteriaceae. The Enterobacteriaceae are a large and diverse group of gram-negative, nonspore-forming bacilli that ferment glucose with the production of acid and usually gas, are oxidase-negative, reduce nitrate to nitrite, and are usually catalase-positive. *E. coli* is peritrichous, meaning that flagella grow from many places on the cell surface. It also often contains a polysaccharide capsule. *E. coli* colonies produce a characteristic 'metallic green sheen' when cultured on eosin methylene blue agar.

E. coli is a member of the indigenous (i.e. normal) intestinal microflora of humans and animals and also is isolated from a variety of environmental sources. It is the bacterium most often isolated from clinical specimens sent to the medical laboratory. In fact, *E. coli* is the most common bacterial type isolated from hospitalized patients with bacteremia/septicemia. The genera *Escherichia*, *Klebsiella*, *Enterobacter*, *Serratia* and *Citrobacter* are collectively referred to as 'coliforms' because of their ability to ferment lactose. The isolation of coliforms from water and other sources by bacteriology laboratories is often used as an indicator of human and animal fecal contamination.

Serotypes (antigenic classification)

The major antigens of *E. coli* are the K, H and O antigens. K antigens are components of the polysaccharide capsule or pilus-like proteins, H antigens are located on flagella, and O antigens compose the outer polysaccharide chains linked to the core lipopolysaccharide (LPS) of the bacterial cell wall of gram-negative bacteria. O antigen specificity is determined by the sugar sequence of the polysaccharide chains. These heat-stable, somatic O antigens commonly identify the serogroup of an *E. coli* strain. More than 170 O antigen *E. coli* serogroups have been identified and there is a relationship between certain *E. coli* serogroups and *E. coli* virulence. For example, *E. coli* O55 serogroup is often associated with human disease.

H antigens (>50) identify the *E. coli* serotype. Thus, *E. coli* serotypes are specific combinations of O and H antigens. *E. coli* O157:H7 is the serotype most recently associated with hemorrhagic colitis, often caused by eating undercooked ground beef. K antigens identify particular *E. coli* strains by their capsule type. For example, *E. coli* K1 is the most common cause of bacteremia/meningitis in infants.

Most *E. coli* also produce heat-labile surface proteins seen microscopically as filamentous structures (called pili or fimbriae) different from flagella and antigenically unrelated to O, H or K antigens. Even with the introduction of new molecular biology methods of *E. coli* classification, serologic typing is still widely used as a convenient method for tracing outbreaks of *E. coli* diarrheal disease.

Virotypes (diarrhea-producing *E. coli*)

Recently, *E. coli* strains have been categorized on the basis of certain virulence factors (i.e. virotyping). This classification scheme is based on the production of certain *E. coli* toxins, patterns of *E. coli* adherence to particular host cells, the abilities of *E. coli* strains to invade the intestinal epithelium, and the patterns of intestinal mucosal pathology produced by *E. coli*. Virotyping therefore more directly relates various *E. coli* strains to the actual disease process than does serotyping. Currently, diarrhea-causing *E. coli* are divided into five virotypes: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC) and enteroaggregative *E. coli* (EAEC). The various properties of these *E. coli* virotypes are presented in **Table 1**.

Enterotoxigenic *E. coli* (ETEC) produce a diarrheal disease similar to that caused by *Vibrio cholerae*, although less severe. Nonetheless, ETEC diarrhea when combined with malnutrition is a major cause of morbidity and mortality in infants and small children during the first 2 years of life in Third World countries. Transmission is through contaminated food and water. Thus, ETEC cause infant diarrhea in the Third World, traveler's diarrhea in both infants and adults traveling from developed to less developed countries, and food poisoning (i.e. gastroenteritis) in infants and adults in both

Table 1 Characteristics *E. coli* virotypes

	ETEC	EPEC	EHEC	EIEC	EAEC
Disease	Infant diarrhea Traveler's diarrhea Gastroenteritis (food poisoning)	Infant diarrhea Traveler's diarrhea Persistent diarrhea in children	Dysentery Hemorrhagic colitis Hemolytic uremic syndrome	Dysentery	Traveler's diarrhea Persistent diarrhea in children
Fever	Usually absent	Present	Absent	Present	Sometimes?
Toxins	LT and ST	No toxins	SLT	No toxins	ST ('EAST')
Primary site	Small intestine	Small intestine	Large intestine	Large intestine	Small intestine?
Invasiveness	Not invasive	Invasive	Not invasive	Invasive	Not invasive
Mucosa pathology	Intact mucosa	'Attaching and effacing' lesions 'Pedestals'	'Attaching and effacing' lesions	Necrosis and ulcerations similar to <i>Shigella</i>	Intact mucosa
Incidence	Common	Common	Rare	Very rare	Fairly rare?

developed and less developed countries. ETEC diarrhea is often misdiagnosed as a viral diarrhea since ETEC are not detected in stool samples by routine microbiology unless special instructions are given to the clinical laboratory.

ETEC produce several types of pili or fimbriae, such as type 1 pili and a number of specialized pili called colonization factor antigens (CFA), that act as mucosal adhesins enabling ETEC to colonize the small intestine. These CFA are plasmid-encoded. Recently, ETEC have been reported to possess a long polar pilus termed 'longus'. Like *V. cholerae*, ETEC adhere to the epithelium in the small intestine but do not usually penetrate the intestinal mucosa.

The pathogenesis of ETEC diarrhea involves the colonization of the small intestine by ETEC followed by the elaboration of diarrheagenic enterotoxins. On the intestinal mucosa, ETEC elaborate a heat-labile enterotoxin (LT) inactivated by heating at 100°C for 30 min and a heat-stable enterotoxin (ST). There are two subtypes of LT: plasmid-encoded LT-1 and chromosome-encoded LT-2. LT-1 shares a high degree of amino acid sequence identity with *V. cholerae* toxin and, like cholera toxin, is a classical AB toxin composed of one A (active) subunit and five B (binding) subunits. The B subunits bind to a specific ganglioside (G_{m1}) on the epithelial cells of the small intestine but are not internalized. The A subunit is subsequently activated by cleavage of a peptide bond and internalized. The A subunit catalyzes the ADP-ribosylation of membrane-bound adenylate cyclase resulting in increased cAMP and increased secretion of fluids and electrolytes. Thus, ETEC produces a watery noninflammatory diarrhea similar to cholera diarrhea.

ST toxins appear to be a group of small peptides ranging from 18 to 50 amino acids in length. ST-I binds to a glycoprotein receptor, thereby activating a membrane-bound guanylate cyclase. The increase

in cGMP increases the secretion of fluids and electrolytes to cause an LT-like watery diarrhea. ST-II appears to cause increased fluid secretion by a different mechanism and has been found so far only in porcine ETEC strains. The small ST peptides are nonimmunogenic.

Enteropathogenic *E. coli* (EPEC) cause only sporadic cases of diarrhea in developed countries but are a major cause of diarrhea in the Third World, especially in children less than 1 year of age. There are three stages in the pathogenesis of EPEC. In the first stage, EPEC attach to epithelial cells in the small intestine by a 'nonintimate' association facilitated by bundle-forming pili (BFP). The genes responsible for this adherence are located on a plasmid called EAF (EPEC adherence factor). EPEC form microcolonies on the intestinal mucosa during this stage. During the second stage, a signal transduction event is triggered in the host epithelial cell which activates host cell tyrosine kinases resulting in increased host cell intracellular calcium. In the third stage, a protein produced by EPEC called intimin allows EPEC to associate more closely with the host epithelial cells ('intimate' association). This association causes rearrangement of host cell actin resulting in deformation and destruction of epithelial microvilli ('effacement') and the formation of 'pedestal-like' structures of filamentous actin on which EPEC rests. This process is therefore called 'attaching and effacing' and the genes involved are designated eae. EPEC do not produce LT or ST and diarrhea is probably a consequence of the damaged intestinal epithelial cells no longer being able to absorb water effectively. It is unclear whether EPEC actually invade the intestinal mucosal barrier.

In developed countries, EPEC diarrhea is limited to occasional outbreaks in nurseries and day-care centers. In less developed countries, however, EPEC diarrhea occurs at a high incidence and a high

mortality, especially in children 6–12 months old. EPEC is also a recognized cause of chronic diarrhea of children in less developed countries.

Enterohemorrhagic *E. coli* (EHEC) possess powerful cytotoxins called Shiga-like toxins (SLT-I and SLT-II), since they are antigenically and functionally similar to the classical Shiga toxin of *Shigella dysenteriae*. SLT-I is identical to Shiga toxin whereas SLT-II is 56% homologous. SLT is an AB type toxin consisting of one A subunit and five B subunits. The B subunits bind to a membrane glycolipid while the A subunit is internalized and causes cell death by enzymatically modifying ribosomal RNA thereby preventing elongation factor 1-dependent binding of amino acyl tRNA.

EHEC can cause attaching and effacing lesions similar to EPEC, but the site of EHEC infection is the colon rather than the small intestine. EHEC SLT causes capillary thrombosis and associated inflammation of the colonic mucosa leading to hemorrhagic colitis. There is an acute inflammatory response and mucosal tissue destruction resulting in bloody diarrhea, the hallmark of hemorrhagic colitis. Symptoms usually resolve in 3–10 days.

E. coli O157:H7 is the EHEC serotype most often associated with hemorrhagic colitis and may produce larger amounts of SLT than other EHEC serotypes. *E. coli* O157:H7 hemorrhagic colitis was first recognized in 1982 and appears most prevalently in the USA in the Pacific Northwest, although cases do occur nationwide. Because of these hemorrhagic colitis outbreaks, hospital laboratories now test specifically for *E. coli* O157:H7. Most cases of *E. coli* O157:H7 have occurred following the ingestion of undercooked ground beef, although other contaminated sources also have been identified. Approximately 1% of apparently healthy cattle carry *E. coli* O157:H7 in their gastrointestinal tracts and meat becomes contaminated during slaughter and in the process of making ground beef. It is now recommended that ground beef be cooked at a temperature of 155°C.

Approximately 13% of patients with hemorrhagic colitis, most commonly children between 1 and 4 years of age, develop a sequelae called hemolytic uremic syndrome (HUS). EHEC toxins can cause direct renal endothelial damage and alter platelet function. The kidney damage may be irreversible and even lead to death. HUS is now the leading cause of acute renal failure in children.

Enteroinvasive *E. coli* (EIEC) is a newly recognized *E. coli* virotype (since 1971). EIEC cause an invasive dysenteric form of diarrheal disease, similar to that of *S. dysenteriae* but less severe. EIEC invade the mucosal epithelium of the colon and multiply, behav-

ing like an intracellular pathogen. No toxins have been identified. Fortunately, EIEC diarrhea is rare, occurring primarily in developed countries in children less than 5 years of age.

Enteraggative *E. coli* (EAEC) is the newest category of diarrhea-causing *E. coli* and, as the name implies, was first recognized because of the aggregation of EAEC *in vivo* on intestinal epithelium and also *in vitro* on certain tissue culture cells. The pathogenesis of EAEC is not understood, but EAEC appear to possess particular adhesins called GVVQP fimbriae, the name derived from the primary amino acid sequence. EAEC also produce a stable toxin called EAST (enteroaggative ST). EAEC may be a cause of so-called persistent diarrhea of infants and young children.

***E. coli* indigenous to the gastrointestinal tract**

E. coli is a member of the indigenous (i.e. normal) microflora (400–500 species) present in the gastrointestinal tract of humans and animals. Indigenous *E. coli* differ from the pathogenic ETEC, EPEC, EHEC, EIEC and EAEC virotypes discussed above. The indigenous *E. coli* are not usually responsible for intestinal infection or diarrhea, but may translocate across the intestinal barrier to cause extraintestinal infections in other tissues and even bacteremia/septicemia. Consequently, indigenous *E. coli* are 'opportunistic' pathogens and can cause disease depending upon increased populations of *E. coli* in the intestines ('intestinal overgrowth') and predisposing host factors, such as compromised immune defenses and increased intestinal permeability. Thus, *E. coli* septicemia in debilitated patients probably originates from the patient's own gastrointestinal tract rather than from *E. coli* contamination from the environment, even if entering via wound sites.

Attempts have been made to associate extraintestinal disease caused by indigenous *E. coli* with certain *E. coli* virulence factors, such as the production of hemolysin, capsule polysaccharide, colicin V, aerobactin, type 1 fimbriae, P fimbriae, and even the presence of certain adhesion operons (pap, sfa, afa, hly). However, it is not possible as yet to relate any of these putative *E. coli* virulence determinants or even a group of determinants with indigenous *E. coli* extraintestinal disease.

Immunity

Immunoglobulin M (IgM) and IgG serum antibodies are readily produced to *E. coli* O, H and K antigens.

More importantly, anti-*E. coli* secretory IgA decreases the adherence of diarrhea-producing *E. coli* in infant intestines. Thus, breastfed infants have a lower incidence of ETEC diarrhea than do bottlefed infants in less developed countries, demonstrating the importance of protective secretory IgA in breast milk (passive immunity).

Adults living in ETEC endemic areas also have a lower incidence of ETEC diarrhea than do travelers to these areas. Repeated episodes of ETEC diarrhea in less developed countries apparently stimulate secretory IgA specific for LT and colonization factor antigens (CFA). Therefore, adults in less developed countries acquire a certain degree of immunity and ETEC diarrhea in less developed countries is primarily a disease of infants and young children.

E. coli vaccines, primarily against ETEC, are presently under development utilizing a variety of approaches. The prophylactic administration of anti-*E. coli* serum antibodies to decrease *E. coli* septicemia in debilitated patients also is under intense investigation but with little success to date. Nonetheless, the immunologic prevention of *E. coli* diarrheal diseases and septicemia would be of tremendous

medical significance in both developed and less developed countries.

EXERCISE AND THE IMMUNE RESPONSE

Laurie Hoffman-Goetz, Department of Health Studies and Gerontology, Faculty of Applied Health Sciences, University of Waterloo, Waterloo, Ontario, Canada

Bente K Pedersen, Department of Infectious Diseases, Rigshospitalet, Copenhagen, Denmark

Exercise induces a variety of coordinated physiological and biochemical responses which dramatically alter the distribution and function of immunocompetent cells. Exercise-associated changes in hormone release, blood flow distribution, cardiac performance and substrate utilization have significant implications for the functioning of the immune system. For example, short, vigorous bouts of exercise (e.g. sprinting), sustained, strenuous exercise (e.g. marathon running), or intermittent, vigorous exercise (e.g. soccer) induce an immediate leukocytosis with white blood cell counts increasing anywhere from two- to eightfold above pre-exercise levels. Immunological changes which accompany exercise are of both fundamental and applied interest. Physiologically, exercise-associated changes in the behavior of immune cells parallel changes induced by other physical stressors, such as thermal injury, hemorrhagic shock, and surgery. From a public health perspective, exercise-induced immunosuppression (or immunoenhance-

ment) may impact on disease risk for some segments of the population.

Exercise and lymphocyte subpopulations

The changes in the types of lymphocytes in the circulation as a result of exercise have been well studied. The absolute number of CD3⁺, CD8⁺ and CD16⁺/CD56⁺ (natural killer, NK) cells increase during and immediately after exercise. B Lymphocytosis also occurs with acute exercise. These increases are transient and return to pre-exercise levels within a few hours of cessation of exercise. The ratio of CD4⁺CD8⁺ lymphocytes (helper/suppressor ratio) decreases immediately after exercise, largely because the CD8 count increases more than the CD4 count. Subject fitness level does little to modify this basic pattern and exercise intensity and duration are the key variables in modifying the extent of the lymphocyte subpopulations shifts. Following acute

exercise, the absolute concentration and *in vitro* cytolytic activity of CD16⁺/CD56⁺ cells increases dramatically. Following exhaustive physical activity, NK cell numbers in blood decrease and cytolytic activity declines. The absolute number of CD45RA⁺45RO⁺ lymphocytes (indicative of cellular activation) increases after endurance exercise.

Exercise and cytokines

Multiple forms of stress elicit an increase in interleukin (IL) concentrations in blood and it is, therefore, not surprising that exercise also induces cytokine release. IL-6, but not IL-1, has consistently been shown to be elevated in plasma after exercise. Blood levels of tumor necrosis factor α (TNF α) and granulocyte-macrophage colony-stimulating factor (GM-CSF) are virtually undetectable after exercise. The concentration of IL-2, an important regulator of T cell function, has been shown to decrease (relative to baseline) after exercise. Interferon α (IFN α) levels are elevated immediately after exercise at 70% of $\dot{V}O_{2\max}$. Urinary excretion of cytokines are probably more indicative of the impact of exercise since elevated blood levels of cytokines usually occur only after severe inflammatory challenge or extensive muscle damage. Elevated urinary concentrations of IFN γ , TNF α and IL-6 have been detected after completion of long-distance running in humans. Despite our understanding of changes in cytokine profiles with exercise, the physiological consequences of altered cytokine profiles in response to exercise are largely unknown.

Exercise and lymphocyte functions

Although exercise induces an increase in the absolute number of leukocytes and changes the lymphocyte subpopulation profile, the functional impact of exercise on immune effectors is equivocal. While there have been an increasing number of investigations in this area, the results are difficult to compare because of variations in protocol methodology, the confounding of exercise effects by circadian hormone patterns, and the heterogeneity in exercise capacity among subjects. These limitations notwithstanding, a number of general patterns emerge regarding exercise and lymphocyte responses.

The most well-characterized lymphocyte response to exercise is that of the cellular proliferation response to mitogens and antigens *in vitro*. The ability of lymphocytes to proliferate to classical T cell mitogens (phytohemagglutinin (PHA), concanavalin A (con A)) is decreased immediately after exercise but returns to baseline levels within 24 h; the

proliferative response to B cell mitogens (lipopolysaccharides, LPS) or mixed T-B cell mitogens (pokeweed mitogen, PWM) increases post-exercise. These proliferative changes do not appear to reflect altered function or activation of individual lymphocytes but are rather due to concurrent numerical changes in lymphocyte subsets. Natural killer (NK) cell (i.e. CD56⁺/CD16⁺) function is markedly affected by exercise above 60% $\dot{V}O_{2\max}$; *in vitro* cytolysis of ⁵¹Cr-labeled tumor cells is suppressed after intense exercise which is due to decreased numbers of NK cells in blood and prostaglandin-mediated suppression. The influence of a single bout of exercise on modulating antibody synthesis is minimal. In trained athletes, high-intensity endurance exercise is associated with a decrease in salivary IgA levels after exercise; levels of secretory IgA in nasal washings remain unchanged. In contrast, basal levels of serum IgG, IgM and IgA, and the capacity to produce antibody to tetanus toxoid antigen is not compromised by exercise.

Endocrine and other mediating mechanisms

Several factors influence the responses that are activated in response to exercise, including immunological experience and many biopsychosocial factors. Despite the diversity of these factors, a stereotypical set of neuroendocrine pathways are critically involved. The dramatic changes in fuel requirements, together with cardiovascular adjustments needed to accomplish the increased demand for muscle tissue oxygen supply, requires a strong regulation in order to maintain internal homeostasis during exercise. Changes in autonomic nervous activity and in hormone secretion are central in this respect. Muscular exercise is associated with an increase in the concentration of a number of stress hormones in the blood including epinephrine, norepinephrine, growth hormone, β -endorphins and cortisol; the concentration of insulin slightly decreases with exercise.

The leukocytosis of exercise (largely a lymphocytosis and neutrophilia) is a consequence of hemodynamic and endocrine effects of exercise mediated by the autonomic nervous system. Norepinephrine release has marked α -adrenergic effects including increased pulmonary blood flow and arteriole vasoconstriction in the viscera. The consequences of α -adrenoceptor stimulation with exercise on lymphoid parameters are twofold. First, although the noncirculating neutrophil and lymphocyte pools in the lungs are small, leukocytes become rapidly demargined with increased lung blood flow. Second, vasoconstriction in the splenic vascular beds lead to a large

initial movement of blood cells into the circulation. The importance of splenic reservoirs and subsequent demargination to exercise leukocytosis remains open since leukocyte number increases in splenectomized individuals as well. Concurrent stimulation of the adrenal medulla results in the release of epinephrine into the plasma with marked β -adrenergic effects. A prominent β -adrenergic effect on the immune system is that of decreased leukocyte–endothelial cell adherence in the viscera; this would also result in a net release of leukocytes from visceral tissues, despite a reduced blood flow to these regions. Taken together, the α - and β -adrenoceptor-mediated effects lead to an increase in circulating leukocytes (leukocytosis) that is characteristic of exercise.

Studies where hormones were infused, hormone receptors were blocked by drugs, or the hormone production was inhibited by epidural blockade in relation to physical stress contribute greatly to our understanding of the mechanisms of action of exercise on the immune system. Epinephrine and, to a lesser degree, norepinephrine are responsible for acute exercise effects on lymphocyte subpopulations. The increase in catecholamines and growth hormone mediate the acute effects on neutrophils, whereas cortisol exerts its effects within a time lag of at least 2 h. Cortisol contributes to the maintenance of lymphopenia and neutrocytosis after exercise of long duration. The role of the endorphins is less clear. β -Endorphin is derived from the same precursor molecule (pro-opiomelanocortin) as adrenocorticotropic hormone (ACTH) and has consistently been shown to enhance NK cell function *in vitro* at concentrations of 10^{-7} – 10^{-9} M; however, based on intervention studies, we do not believe that β -endorphin plays a major role in the immediate recruitment of leukocytes to the blood; β -endorphin may be important, however, in chronic training stress.

Substrate availability is another potential factor to consider in exercise–immune cell interactions. Glutamine is required for lymphocyte mitogenic responses and it has been suggested that skeletal muscle plays a regulatory role for the synthesis and release of glutamine. The so-called ‘glutamine hypothesis’ suggests that with intense or prolonged physical activity, the demand for glutamine by immune (and other) cells is greater than the anabolic capacity of skeletal muscles to produce glutamine; the consequence is a glutamine debt and immunosuppression. Experimental support for this hypothesis has been inconsistent.

Exercise and immunity

An important question is to what degree exercise-associated changes in immune function are of clinical significance, e.g. whether exercise influences the resistance to acute or chronic diseases that have an immunological component either in etiology or pathogenesis. Clinical relevance of exercise-mediated immunomodulation has been harder to demonstrate than the phenomenological aspects.

It has been known for about 100 years that exercise or training before exposure to infection decreases morbidity or mortality, whereas exercise during the infection has the opposite effect. Thus, acute exercise to exhaustion after infecting laboratory animals with anthrax bacilli or *Streptococcus pyogenes* resulted in increased mortality compared to sedentary controls. In contrast, repeated exposures to exercise prior to exposure with type 1 *Pneumococcus* was associated with reduced mortality in experimental animals relative to sedentary controls. Epidemiological studies suggest that the relative risk for upper respiratory tract infections (URTI) is increased during and for 1–2 weeks following overtraining or marathon-type exercise in endurance athletes. Since prolonged, intense exercise is also associated with some immune suppression, this has led to the ‘open window’ hypothesis (Figure 1). This hypothesis suggests that during the period immediately following heavy and prolonged training, host immunity is suppressed and risk of URTI is elevated. Testing of this hypothesis will require investigations with necessary methodological rigour (e.g. in selection of appropriate control groups) including adjustment for confounders (such as season and air temperature) and potential bias (such as selection and recall bias) which have limited the conclusions of existing studies in this area.

Figure 1 During moderate and intense exercise lymphocytes are recruited to the blood and the NK cell activity increases. Intense, prolonged exercise is followed by immunodepression (lymphopenia, suppressed NK cell activity, reduced production of secretory IgA) during which there is an ‘open window’ of opportunity for pathogens.

Although the empirical evidence concerning exercise and most types of cancer is limited, over 25 epidemiological studies have been conducted to investigate relationships between exercise and colon cancer; there are also a handful of animal studies on exercise and colon cancer. Despite varying designs, study populations, and measures of exercise, the vast majority demonstrate small, but consistent, increases in risk for colon cancer with physical inactivity. Far fewer studies on the effect of physical activity (or inactivity) on risk of breast and prostate cancer have been conducted; the limited results suggest the same magnitude and direction of association as observed with colon cancer (i.e. risk estimates ranging from 1.1 to 2.0 for physical inactivity). Endocrine rather than immunological mechanisms have been proposed for these findings, although further research is warranted.

Animal models point to the importance of timing of exercise and the intensity of exercise in modulating tumor growth. Early reports, in which rodents were exercised intensively prior to establishment of tumors, describe inhibition of tumor growth (sarcomas and carcinomas). Growth of an experimental hepatoma was decreased in rats given mild-to-moderate swim exercise after tumor implantation. Rat and mouse models suggest a potential role for exercise in controlling tumor metastasis. Baseline elevations in NK cell and macrophage cytolytic functions with endurance training have been linked to reduced experimental lung tumor burden and greater *in vivo* clearance of radiolabeled tumor cells.

There is no evidence to date that exercise in humans modifies the onset of autoimmune diseases. In animals, however, exercise before disease onset generally does not exacerbate the clinical signs of autoimmune disease, except for experimental autoimmune myocarditis.

Concluding comments

Despite limitations in the design and comparability of current exercise immunology research, it is apparent that physical exercise modifies a number of immune parameters. This is not unexpected since the

neuroendocrine changes accompanying exercise parallel those neuroendocrine changes which occur in response to other physical (and psychological) stressors. Thus, exercise immunology should be viewed as a specialized focus within the larger theme of neuroendocrine-immune interactions.

Many studies have described the impact of exercise on the immune system (for example, in 1993–1994 over 150 papers were published on exercise immunology). However, what remains unclear is the clinical impact of exercise-induced changes in immune function. While elite athletes may be at risk for more frequent or sustained episodes of immunosuppression, understanding the subtle and transient changes which accompany moderate exercise (and which have potentially far greater implications for population health) will require additional research efforts.

EXOCYTOSIS

Jacques Padawer, Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, New York, USA

Exocytosis is a universal cellular process operative in plants, protozoa, invertebrates and vertebrates alike. It is essential for cellular differentiation and function, and intimately dependent on molecular constitution and cytomorphology. Originally, it referred narrowly to extracellular release of cell products and was termed *secretion*, *eccytosis* or *emiocytosis*. Commonly, secretion products are confined intracellularly within fluid or storage granule vesicles that fuse with the plasmalemma, and the term *exocytosis* can refer strictly to that ultimate vesicular extrusion step, or can be broadened to embody the entire functional anterograde path from site of synthesis to plasmalemmal fusion, irrespective of vesicular content(s) or membrane composition and whether granular products are released extracellularly in addition to membrane insertion into the plasmalemma.

Historical background

Cellular engulfment of solid particles via vesicles (phagocytosis) was first reported in the late 1800s. Vesicular fluid intake (pinocytosis) was described subsequently. These activities implied a large consumption of cell surface membrane, but biochemical studies in the 1950s failed to demonstrate commensurate lipid biosynthesis. This led to the concept of membrane recycling linking *endocytosis* (both phago- and pinocytosis) to *exocytosis*, respectively vesicular uptake or discharge of matter, whereby membrane segments are concomitantly respectively withdrawn from or added to the plasmalemma. Anterograde membrane flow (from cell center to plasmalemma) can originate from various organelles but ultimately homes in at specific domains of the cell surface. Membrane flow serves several functions and is involved in 1) membrane conservation, 2) endocytosis, 3) discharge from the cell of synthesized, metabolized or unmetabolizable materials, 4) transcellular transport, and 5) withdrawal from, or insertion into, the plasmalemma of lipids and integral membrane proteins, a quasisecretion process *didactically designated in this overview* as 'm(membrane)-exocytosis' to distinguish it from 's(cretion)-exocytosis', i.e. secretion/extrusion of vesicular serous or granular contents into the extracellular space. 'Exocytosis' normally refers to both of these variants. Although s-exocytosis can not occur independently of m-exocytosis, the converse can. The

term 'secretion' is more general; it does not necessarily involve vesicle-membrane fusion and presents semantic conundrums ascribable to different vocabularies of histophysiology and molecular biology; it includes 1) discharge of proenzymes from pancreatic acinar cells (merocrine secretion), 2) release of serous mixtures from sweat glands (eccrine secretion), 3) shedding of lipid from active mammary alveoli (apocrine secretion), and 4) spilling of contents upon cell death in sebaceous glands (holocrine secretion), but excludes kindred processes euphemistically called 1) 'externalization' of product-laden membrane evaginations (matrix components of cartilage and bone, some viruses, myoblast lectin), 2) 'expulsion' of nuclei from erythroblasts, or 3) 'shedding' of platelets by megakaryocytes.

Cytomorphologic infrastructure of exocytosis

Eukaryotic cells feature various membrane-delimited sacs embedded in a structured cytoplasmic matrix. These form a coherent set interconnected morphologically or via vesicular transport, thereby establishing a functionally continuous vectorial *cisternal space* (Figure 1), embedded within but topologically distinct from the cytoplasm, 'outside' the cell much as our digestive tract is topologically 'outside' our body. The cisternal space includes 1) the nuclear envelope, a perforated double-membraned sac continuous with 2) the endoplasmic reticulum, partly studded with ribosomes proximally (rough ER, RER), but not so distally (smooth ER, SER), 3) the Golgi apparatus, a set of flattened sacs shaped like soup plates nested within each other that, among other functions, encapsulates cell products into 4) membranous intracellular transport vesicles. Free cytosolic polyribosomes synthesize constitutional proteins (cytoskeletal elements, cytoplasmic enzymes, dedicated proteins such as hemoglobin). Proteins destined 'for export', i.e. m- and s-exocytosis, are synthesized by polyribosomes attached to the RER and are either anchored within the RER membrane or extruded *in toto* into the cisternal space, whence they are translocated through the Golgi apparatus for post-translational modification and/or packaging, then sorted in the trans-Golgi network into either exocytotic vesicles or lysosomes. Exocytotic vesicles with or without cargos of

Figure 1 Exocytotic morphologic pathways for A, m-exocytotic insertion of integral membrane proteins (synaptic choline esterase, insulin or cholesterol receptors, cell attachments) and lipids (cholesterol, glyco- and phospholipids), or B, export/secretion (s-exocytosis) outside the cell. Pathway A is an obligate component of pathway B, but not vice versa. The left side of the diagram emphasizes consistency of polarity between inner and outer membrane leaflets, the right side continuity of the cisternal spaces. Integral membrane proteins (receptors, enzymes, ion gates, active transport) and glycolipids remain anchored within the lipid membranes (left side of diagram). The ultimate destination of most such proteins is the plasmalemma, although some associate with Golgi stacks, lysosomes, peroxisomes, etc. By contrast, proteins destined for release into the extracellular compartment are first injected *in toto* into the RER cisternal space and are ultimately conveyed, via contiguous segments of the cisternal space, to s-exocytotic vesicles, some propelled by cytoplasmic kinesin motor proteins to the plasmalemma along microtubules originating from the centrosome. When s-exocytotic vesicles/granules fuse with the cell surface, their membranes insert into the plasmalemma and their contents spill passively out of the cell. TGN, trans-Golgi network; RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum; +, growing ends of microtubules. Note that s- and m-endocytosis are one and the same process that here has been dissociated for didactic purposes to emphasize the overlapping though different end-points.

specific secretory products (peptide hormones, proenzymes, etc.) first bud off from the ER, join and traverse the Golgi, and bud off again from the trans-Golgi network. Exocytotic vesicular traffic within the cell is either undirected, with docking determined by chance contacts between associated complementary targeting and accepting molecules (Table 1) on vesicular and plasmalemmal membranes, or directed to appropriate cell surface domains by cytoskeletal fibers (microtubules, actin and intermediate filaments, each associated with helper proteins modulated by specific biochemical reactions (Figure 2). s-Exocytosis occurs 1) of zymogen granules by gastric chief cells at the apical surface, 2) of chylomicra by enterocytes, at the lateral membrane behind the junctional complexes that anchor epithelial cells to each other, restrict membrane flow between apical and basolateral domains, and insulate tissue spaces from lumina, and 3) of plasma components for transfer into tissues across endothelia, at the basal cell surface. Endocytic vacuoles can be translocated to primary lysosomes (Figure 3) where fusion of the two yields secondary lysosomes, thence back to the cell surface, a path characteristic of receptor-mediated phagocytosis; their receptors can be recycled. Polarized motor proteins, cytoplasmic dyneins and kinesins, translocate some vesicles along microtubules toward or away from the cell center, respectively, but other mechanisms may exist. Interference with microtubule assembly by colchicine impedes secretion of pancreatic zymogens, parathormone and fibroblast procollagen.

s-Exocytosis to the extracellular space

s-Exocytosis can be *regulated* or *constitutive*. Regulated exocytosis occurs on demand via secretagogues and signal transduction. Constitutive exocytosis is continuous; no secretagogue is involved, there are no storage vesicles, and the products are released apace upon synthesis. s-Exocytosed products of nonneuronal cells (digestive proenzymes, peptide hormones, immunoglobulins, chylomicra lipoproteins) originate in the RER, are carried by vesicles to and through the Golgi apparatus, then by vesicles or membrane-bounded granules to the plasmalemma, and are finally extruded by fusion of the vesicles with the cell membrane. For that entire transit they remain confined topologically within the cisternal space (Figure 1). In neurons some vesicles recycle and reload near the synapse. In pancreatic acini, fusion of progressively deeper granules with more peripheral ones, called *sequential* or *compound exocytosis*, forms extended extrusion channels, also said to occur in mast cells. Various agents elicit release of mast

cell mediators: Ca^{2+} ionophores, cross-linkers of immunoglobulin E (IgE) receptors on the cell surface by antigen, polycations or some lectins. Phagocytosis of negatively-charged thorium dioxide particles or plastic beads by rat serosal mast cells delivers them over time via endosomes to young, then mature granules, without causing degranulation. The metal is retained for months and migrates between granules, which change their staining properties as the cell ages. They have *in situ* enzymatic activity (and *ipso facto* function?), and their mediators have long half-lives. Polylysine causes degranulation. Cationic (polylysine-coated) beads breach the granular sac by a different path that bypasses endosome vesicles, and they contact mature granules directly without delay. All this argues for a transient or permanent membranous sac enfolding multiple granules in a way unrelated, if morphologically resembling, sequential exocytosis. Could IgE antigens act as *pathologic* mast cell secretagogues? This paradoxical dichotomy suggests that mast cell degranulation interferes with a primary intracellular function, whatever that might be, and that evidence for compound exocytosis must be interpreted cautiously.

At plasmalemmal docking sites, a series of biochemical signaling reactions involving G protein(s), enzymes, phosphoinositol metabolites, etc. may lead to transient shifts of ionic calcium into cells and/or between some intracellular compartments. These Ca^{2+} shifts may not be obligate steps for all cells or all s-exocytotic processes. As fusion of a vesicle with the cell membrane establishes continuity between vesicular contents and extracellular space, all the contents stored within are disgorged simultaneously (epinephrine, enkephalins, chromogranins, nucleotides, etc., by adrenal chromaffin cells), faster and in much higher concentrations than possible via active transport mechanisms. Vesicular pathways can couple endocytosis with s-exocytosis to transport material across a cell (endothelium, kidney tubules) by *transcytosis*. Though uptake at one surface may be selective, there need be no modification of the vesicular contents before s-exocytosis at another surface. Capillary endothelium transfers bulk plasma into tissue spaces, and selected substances across the blood-brain barrier. IgA and IgM are moved across enterocytes in the opposite direction, from basal to apical surfaces.

m-Exocytosis to the cell membrane

Membrane traffic is critical for defining cell type and function which depend on plasmalemmal

Table 1 Some identified components of the membrane fusion machinery in exocytosis and endocytosis^a

1. Vesicular coats -- shape membranes into vesicles	
Clathrin	Trimeric protein complexes that shape budding vesicles. Forms triskelion cages under coated pits, endocytic vesicles, and buds on trans-Golgi membranes
Coatomer	Coat protomer. Non-clathrin polypeptides condensations around shuttling cytoplasmic vesicles. At least seven COP components recognized; form stoichiometric complexes with ARF. Drives vesicle blistering of Golgi membranes
COP1 coats	Coat Proteins forming ARF-coatomer complexes around vesicles that shuttle between ER and cis-Golgi, and vice versa. Unstable; assembled by ARF-GTP
COP2 coats	As COP1, but stable. Assembled by ARF-GTP. Dissociated by hsp70 or SAR1 ATPases. Direct vesicles from ER to cis-Golgi
ARFs	ADP-Ribosylation Factors that regulate vesicular coat structures. These GTPases assemble with COPs to trigger formation of coatomers. Bind to Golgi membranes and cause vesicle budding or uncoating. ARFs are myristylated; they are cytosolic (water soluble) in GDP form, but membrane bound (water insoluble) in GTP form
AP1	Assembly Polypeptide. ARF-dependent complex vesicular protein coat promoting direct transport from trans-most Golgi cisterna to lysosomes. Associated with clathrin
AP2s	Family of Assembly Polypeptides. ARF-independent stable clathrin-associated protein complexes. Associated with coated pits, endocytotic vacuoles, and presynaptic plasmalemma of nerves
SAR proteins	ARF-like G-protein ATPases
Rab proteins	Family ($n = 30+$) of small (22–27 kDa) G proteins with GTPase activity; required for assembly of SNARE complexes. Associated with multiple stages of vesicular cytoplasmic traffic in exocytotic and endocytotic pathways. Regulate or trigger secretion (of enzymes, hormones, neurotransmitters, etc.) via stimulation or inhibition
Annexin XIII	Nonmembrane protein implicated in vesicle transport to apical plasmalemma
TAP (p115)	Protein needed for docking and fusion of transcytotic vesicles to apical cell membrane as well as transport of vesicles between Golgi stacks
2. Membrane targeting and docking	
v-SNAREs	Family of vesicular integral membrane coat proteins that act as destination codes with affinity for cognate SNAP receptors on target membranes. Effect docking with t-SNAREs
t-SNAREs	Family of SNAPs–NSF complexes. Integral membrane proteins that act as destination codes in receptive target membranes. Act as SNAPs receptors to effect docking of specific v-SNAREs
VAMPs	Family of Vesicle-Associated Membrane Proteins. Synaptosome-associated integral membrane protein of brain (synaptobrevin) involved in neurotransmitter release; associated with dense-core vesicles (loaded and recycled at trans-Golgi, in perikaryon) and with small vesicles (loaded and recycled at neuron terminal). Also present in gastric parietal cells, zymogen and chromaffin granules, and yeast
Syntaxins	Integral membrane proteins present in presynaptic plasmalemma, gastric parietal cells and yeasts
3. Membrane fusion	
NSFs	Family of NEM-Sensitive Fusion ATPase proteins. Complex with SNAPs and SNAREs to effect vesicle fusion. Associated with ER, Golgi, plasmalemma and endosomes.
SNAPs	Soluble NSF Attachment Proteins. Colocalize with NSF and SNAREs to elicit fusion of intracellular membranes in animals and yeasts. Associated with Golgi membranes
SNAP25	SyNaptosome-Associated Protein 25 kDa. A presynaptic peripheral membrane protein (structurally unrelated to SNAPs) involved in neurotransmitter release upon local Ca^{2+} influx into the nerve. Induces rapid axonal transport. In gastric parietal cells, elicits expression of H^{+}/K^{+} -ATPase and K^{+}/Cl^{-} channels on surface of extended microvilli to activate HCl secretion.
Synaptotagmins (p65)	Family of integral membrane proteins, primary Ca^{2+} receptors of presynaptic plasmalemma. Inhibit neurotransmitter release. Also implicated in recycling of dense-core neuropeptide vesicles and clathrin-coated small synaptic vesicles at nerve terminals. Interacts with AP2, syntaxin, calmodulin and phospholipids. Involved in both exocytosis and endocytosis. Synaptotagmins can effect both positive and negative regulation of neurotransmitters. Also present in fibroblasts
Synaptophysins	Family of integral membrane proteins of small synaptic vesicles. May enhance exocytosis. Nonneuronal homologs reported in fibroblasts and other cells

Table 1 Continued

4. Ancillary agents	
Nucleotides	GTP and ATP. Cytosolic energy sources for assembly and disassembly of coat proteins in conjunction with GTPases and ATPases. Induce conformational changes in specific molecules
Ca ²⁺ ion	Second messenger for many exocytotic and endocytotic processes, including release of neurotransmitters
c-AMP	Second messenger in many transduction signaling processes
Secretagogues	Primary agents (polypeptide hormones, catecholamines, etc.) that trigger exocytosis by cognate cells. Generally specific ligands for target cell receptors
Fatty acyl-CoA	Alter water/lipid solubility of G proteins and effects membrane detachment/attachment
Proton pumps	ATPases that acidify endosome-lysosome vesicles to activate lysosomal enzymes and dissociate ligands from receptors
Kinesins	Family of protein motors effecting anterograde translocation of transport vesicles along microtubules
Cytoplasmic dyneins	Family of protein motors effecting retrograde translocation of transport vesicles along microtubules
Shaperones	Proteins (e.g. hsp70) that control folding/unfolding of proteins in exocytotic processes

^aCurrent status of participating agents in intracellular vesicular membrane traffic: factual, putative and hypothetical. Entries are not necessarily operative in all cell types, and their specific properties/role(s) are not fully elucidated. The proteins involved in the highly specific and complex processes that lead to exocytosis are members of families of homologous proteins represented in all eukaryotic cells. The mechanisms of transport, docking, fusion and exocytosis are highly conserved from yeast to mammalia, albeit with some specializations and/or variations among cell types and species, with many isoforms present in given species, tissues, cells and even single vesicles. The table includes only a few of the plethora of reported agents. Many additional ones unquestionably will be characterized in this rapidly-developing research area.

differentiation and maintenance. It modulates up-/downregulation of surface receptors involved in signaling and thus actuates switches that control cell function. Cell membranes present domains of differing composition and functions; they assure epithelial polarity which, when disturbed, can lead to severe pathology. The plasmalemma is a mosaic of integral proteins floating in a bilayer of hydrophobic lipids. Intracellular membranes define various aqueous compartments within the cytoplasm. For m-exocytosis the proteins, synthesized by the RER, remain anchored in a polarized orientation within the lipid bilayer by means of hydrophobic sequences in their molecular backbone; they can diffuse laterally within the plane of the membrane, but can not flip-flop. Proteins that project into the cisternal space can be glycosylated or otherwise modified post-translationally. m-Exocytosis of vesicles budded off the trans-Golgi network is the vehicle for translocating these molecules from their site of synthesis to their site of function at the plasmalemma. It insures that their orientation in the membrane is retained during translocation to and fusion with specific domains of the cell membrane, in which they may then diffuse or aggregate laterally to form specialized functional sites (enzyme or transport proteins at the tip of enterocyte microvilli, ion channels, receptors, integrin binding sites for fibronectin) or components of cell-cell junctions (desmosomes, synapses, tight, gap and neuromuscular junctions). Lipids and glycolipids made by the ER-Golgi complex are translocated similarly. Membrane differentiation gives cells their individuality and many of their special functions. It is how cells develop functionally different apical,

lateral and basal surfaces, express specific surface molecules (ABO antigens, receptors) or recognition surface proteins (T lymphocytes).

Membrane flow and conservation

Membrane traffic is essential to the dynamic responsiveness of cells. Plasmalemmal turnover can be massive and very rapid. Because membrane augmentation by exocytosis is coupled with endocytosis, which withdraws membrane from the cell surface, an equilibrium is established and membrane components can be efficiently conserved, added, removed, replenished, changed or recycled. Extracellular ligands snagged by surface receptors can be drawn into the cytosol by endosomes that fuse with lysosomes and become acidified, thereby dissociating ligand from receptor. Dysjunction of the endosome-lysosome complex yields a digestive vesicle and a shuttling receptor-carrier vesicle that can rejoin the plasmalemma via m-exocytosis for another cycle (Figure 3). Normal topological relations are unaffected in those exchanges, as critical membrane polarity is retained (Figure 1). Lastly, massive fusion of exocytotic vesicles can effect cell shape changes (yeast shmooing (formation of pear-shaped cells during mating), microvilli extrusion in activated gastric parietal cells).

The above discussion clearly points to the central role of exocytosis in the very existence of living cells. DNA directs synthesis of cell constituents that establish cellular ultrastructure, but it is cell structure that, via exocytosis, executes the myriad processes that

Figure 2 Targeting/capture of m-exocytotic and s-exocytotic vesicles to/by specialized cell membrane domains. A polarized epithelial cell is depicted, but many of the same features are found in other cell types (neurons, macrophages, lymphocytes, yeast). A, Transfer of substances across an epithelial cell (endothelium, kidney tubule) via a transcellular path from apical (endocytosis) to basal (s-exocytosis) domains; B, uptake of extracellular material (endocytosis) for transfer to luminal space (s-exocytosis) from basal to luminal domains (IgA, IgM across enterocyte); C, m-exocytosis of integral membrane protein (uncharacterized) to tight junction between lateral domains of abutting epithelial cell membranes; D, m-exocytosis of adhesion integral membrane proteins (CAMs, integrins) to form spot and belt desmosomes and hemidesmosomes at lateral and basal membrane domains; E, m-exocytosis of integral membrane proteins (connexin) to communicating (electrotonic) gap junctions in the lateral domain of abutting cells; F, m-exocytosis of receptors to basal membrane (binding to fibronectins, glycosaminoproteoglycans, intermediate filaments). Specialized cell junctions are transient in that they can be withdrawn and restored rapidly under appropriate conditions. The bimolecular unit membranes are drawn as a single line. Note that s- and m-endocytosis are one and the same process that here has been dissociated for didactic purposes to emphasize the overlapping though different end-points.

Figure 3 Endocytosis–exocytosis coupling, membrane conservation and receptor recycling. Integral membrane proteins such as receptors delivered to the plasma membrane by m-exocytosis (Figure 1) bind specific ligands, and the complexes then aggregate into clathrin triskelions-coated pits that are internalized by endocytosis of vesicles linked to and pulled off the plasmalemma by actin filaments. After internalization, the triskelion cage depolymerizes and the vesicle connects to microtubules via cytoplasmic dynein motor proteins that move it along retrogradely. The vesicles join and fuse with lysosomes shed off the trans-Golgi network and propelled anterogradely by kinesin motor proteins, also along microtubules. The fused vesicles become acidified by an ATP-driven proton pump, the receptor–ligand complex dissociates and the lysosome–vesicle organelle (secondary lysosome) reseparates into lysosome and vesicle moieties. The freed ligand, sequestered within the secondary lysosome, is degraded by acid hydrolases, while the receptors sequestered within the regenerated m-exocytotic vesicle membrane are translocated back to the plasmalemma for recycling. TGN, trans-Golgi network complex; H⁺, proton; enz, lysosomal enzymes; triskelions, clathrin trimers. Note that s- and m-endocytosis are one and the same process that here has been dissociated for didactic purposes to emphasize the overlapping though different end-points.

EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Robert H Swanborg, Department of Immunology and Microbiology, Wayne State University School of Medicine, Detroit, Michigan, USA

Experimental autoimmune encephalomyelitis (EAE) is an inflammatory disease of the central nervous system (CNS) which can be induced in susceptible strains of laboratory animals by immunization with CNS antigens. It is characterized clinically by ascending paralysis, and pathologically by perivascular mononuclear cell infiltration and demyelination in the brain and spinal cord. Although EAE is an experimental disease of laboratory animals, it was first observed in humans when, over a century ago,

it was reported that a small percentage of patients receiving Pasteur's rabies vaccine developed neuro-paralytic signs. The rabies virus vaccine was prepared in rabbit CNS tissue. That CNS antigens contaminating the vaccine preparations were probably responsible for the neurological side-effects of the vaccine was demonstrated in the 1930s, by Rivers and his colleagues, who reported that repeated intramuscular injection of extracts of normal rabbit brain (i.e. without rabies virus) induced pathologic changes

in the brains of monkeys; these changes resembled the CNS disease that occurred in humans subsequent to rabies vaccine treatment. With the development of Freund's adjuvant in the 1940s, it became possible to reproducibly elicit EAE in a majority of animals after a single injection of CNS extract emulsified in the adjuvant preparation.

Encephalitogenic antigens

Experimental evidence to support the hypothesis that CNS tissue contains organ-specific antigens capable of eliciting an immune response was first provided by Witebsky and Steinfeld in 1928. Thus, once the EAE model had emerged, a widespread search was initiated to identify the relevant organ-specific antigens responsible for this autoimmune disease. It is known today that two myelin structural proteins, myelin basic protein (MBP) and proteolipid protein (PLP), are the major encephalitogenic antigens (Figure 1). MBP, which constitutes 30% of the total myelin protein, was first reported to induce EAE by Marian Kies in the early 1960s. This antigen actually

consists of a series of differently charged isomers. The predominant form has a molecular weight of 18.5 kDa, and consists of approximately 169 amino acids. MBP is highly conserved, although minor structural variations occur from species to species. This variation influences the encephalitogenic activity of the MBP molecule in different animal species (Figure 1). Furthermore, in rodents, a smaller 14.5 kDa molecule is produced in addition to the 18.5 kDa MBP molecule, as a result of differential RNA splicing of the MBP gene.

The MBP molecule has been extensively studied, and the amino acid sequences of MBP derived from many species have been elucidated. Furthermore, the major encephalitogenic epitopes have been located, and synthetic peptides corresponding to these determinants have been prepared and shown to induce EAE in experimental animals. Of importance is the finding that different sequences are responsible for EAE in different species. Thus, the major encephalitogenic MBP epitope for the susceptible Lewis rat resides in the sequence delineated by amino acid residues 68–86, and a second, minor, epitope exists

Figure 1 Amino acid sequences of major encephalitogenic CNS antigens. (A) The sequences of the 18.5 kDa isoforms of bovine (Bov) and guinea pig (GP) MBP molecules aligned for maximal homology. The N-terminal alanine residue is acetylated. Slight structural variations influence encephalitogenic activity in different animal species, e.g., Bov MBP is relatively nonencephalitogenic for Lewis rats because the addition of GH (underlined) in the dominant 68–86 epitope inhibits recognition by V β 8.2 positive autoreactive T cells. (B) The sequence of the bovine PLP molecule, which is highly conserved in all mammalian species. Single letter abbreviations for the amino acids are: A, Ala; C, Cys; D, Asp; E, Glu; F, Phe; G, Gly; H, His; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; W, Trp; Y, Tyr.

within MBP residues 87–99. In susceptible PL/J mice, the dominant encephalitogenic MBP epitope is located within the N-terminal end of the molecule, more specifically within residues 1–9. The response of Lewis rats and PL/J mice to MBP illustrates the species variability that exists with respect to encephalitogenic epitopes. This variation even extends to different strains within a species. Thus, whereas the PL/J mouse responds to MBP epitope 1–9, encephalitogenic epitopes for the susceptible SJL/J mouse strain are contained within MBP sequence 89–101 (Table 1).

Although MBP was the first encephalitogenic antigen to be characterized and studied extensively, the isolation of PLP predates MBP by over a decade. Folch and Lees first described PLP in 1951, and subsequently attributed encephalitogenic activity to this molecule. PLP constitutes 50% of the myelin protein. It is a 29.8 kDa molecule that consists of 276 amino acid residues, but is water insoluble. This characteristic has hampered the investigation of PLP, and for many years it was argued that the encephalitogenic activity ascribed to this molecule was due to contamination with MBP. However, recent studies with synthetic PLP peptides have clearly established that PLP is a potent encephalitogenic antigen for many species, including rats and mice. Several PLP epitopes have been located within the molecule, and strain variations have also been reported (Table 1).

Although PLP and MBP are the major encephalitogenic antigens, it has been reported that EAE can also be elicited by myelin oligodendrocyte glycoprotein (MOG), and it is conceivable that other CNS constituents will eventually also be shown to be capable of inducing autoimmune CNS disease.

Immunopathology of EAE

Philip Paterson made the important observation in 1960 that EAE can be transferred with viable lymphocytes from immunized donor animals, whereas attempts to transfer the disease with serum containing antibodies against CNS antigens have been

unsuccessful. These findings provided the first indication that cell-mediated immunity is important in the pathogenesis of this autoimmune disease. A major advance in our understanding of the nature of the effector mechanism underlying EAE came about when it was discovered by Panitch and McFarlin, and by Richert and his colleagues, that adoptive transfer could be dramatically enhanced if donor lymphocytes were activated *in vitro* with concanavalin A or MBP prior to transfer to recipients. Subsequently, we used this method to determine that the disease-inducing effector cells in the *in vitro* activated population are CD4⁺ T cells. A major advance came when Ben-Nun, Cohen and Wekerle first established long-term encephalitogenic rat T cell lines, thus permitting detailed analyses of the disease-inducing cell population. Today, many investigators are utilizing clones of encephalitogenic mouse and rat T cells to gain insight into the pathogenesis of autoimmune CNS disease. T cell clones reactive against MBP and PLP have also been isolated from multiple sclerosis (MS) patients, although T cells that react with these neuroantigens are reportedly also found in healthy individuals.

In susceptible rats, EAE is usually an acute disease, characterized by ascending paralysis from which the animal eventually recovers. After recovery, the rat is resistant to further attempts to reinduce the disease. The histopathologic features of EAE in the rat include meningeal, perivascular and parenchymal mononuclear cell infiltration in the CNS, with lesions prevalent in the spinal cord. Demyelination is not pronounced, perhaps because of the acute nature of the disease. A major advantage to the use of rats is the ease of induction and predictable time of onset and recovery from EAE with low doses of MBP in Freund's adjuvant.

EAE is more difficult to induce in mice, and ancillary adjuvants are often required, e.g., pertussis vaccine. In SJL/J and PL/J mice, a chronic relapsing form of EAE (CREAE) has been reported following immunization with neuroantigen and adjuvants, or after adoptive transfer of encephalitogenic T cells. CREAE resembles the exacerbating–remitting form of MS in its cyclical pattern, and demyelination is a prominent feature of both diseases. This makes CREAE a particularly attractive investigational model. CREAE has also been reported in rats, but is generally more difficult to induce than in mice.

The inflammatory lesions in both acute and relapsing forms of EAE contain CD4⁺ and CD8⁺ T cells and macrophages; B cells and plasma cells may also be present. Encephalitogenic T cells are present in the lesions. These can be isolated and have been shown to adoptively transfer EAE to recipients. However,

Table 1 Encephalitogenic myelin epitopes for rats and mice

Species (strain)	Encephalitogenic epitope
Rat (Lewis)	MBP 68–86 (dominant) MBP 87–99 (minor)
Mouse (PL/J)	MBP 1–9 (dominant) ^a PLP 43–64
Mouse (SJL/J)	MBP 89–101 (dominant) ^a PLP 43–64 and other PLP epitopes

^aMinor encephalitogenic epitopes have also been described.

only a small percentage of the cells present in the lesions in transferred EAE are of donor origin, suggesting that many of the infiltrating cells are 'bystander' cells which are recruited into the CNS.

Although the presence of encephalitogenic T cells in the CNS of animals with EAE directly implicates them in the pathogenesis of this disease, the mechanism by which they exert their immunopathologic effect remains to be elucidated. The CD4⁺ T cells that mediate EAE secrete the inflammatory cytokines interferon γ (IFN γ) and lymphotoxin (also known as tumor necrosis factor β), and thus appear to belong to the T_H1 subset which mediates delayed hypersensitivity reactions. Early events in the immunopathologic process include the upregulation, probably by IFN γ , of adhesion molecules and major histocompatibility complex (MHC) class II molecules on the cerebrovascular endothelial cells in the CNS. This presumably facilitates the attachment and penetration of activated encephalitogenic T cells into the CNS. Once these cells have crossed the blood-brain barrier, it is postulated that they recruit bystander cells and secrete cytokines (e.g. lymphotoxin), which promote inflammation. Recent evidence has also implicated prostaglandins, nitric oxide and chemokines in the pathogenesis of EAE. These molecules are produced by the inflammatory cells, e.g. macrophages, within the CNS lesions.

Genetics of EAE

In most species, a strong association exists between susceptibility to EAE and MHC haplotype. The response to a given encephalitogenic determinant is governed by the MHC class II gene products, and the T cell receptor (TCR) repertoire available to the animal (Table 2). For example, the response of PL/J mice to MBP 1–9 is restricted by MHC I-A^U, and the responding T cells preferentially use V α 2 or V α 4 and V β 8.2 in their TCR. SJL/J mice recognize two epitopes within MBP 89–101 in the context of I-A^S, and 50% of the responding T cells express the V β 17a TCR. Lewis rats recognize the dominant encephalitogenic epitope (MBP 68–86) in the context of

RT-1B^I (the rat equivalent of murine I-A), and the majority of encephalitogenic T cells express V α 2 and V β 8.2. In contrast, the response to MBP epitope 87–99 is restricted by RT-1D^I (i.e. the homolog of murine I-E), and the responding T cells express diverse V region gene products. Thus, it seems clear that susceptibility to EAE is governed by both MHC and TCR gene products which recognize defined MBP epitopes. Murine encephalitogenic responses to PLP determinants are also restricted by MHC class II, but Sobel and his colleagues have shown that TCR receptor usage is diverse.

Regulation of EAE

EAE has also served as an important model for the investigation of potential therapeutic strategies for human demyelinating diseases. Alvord and his colleagues reported in 1965 that EAE is inhibited in animals tolerized to MBP. This approach has been exploited over the years and, depending upon the tolerization protocol, the inhibitory effect can be attributed either to clonal anergy or active suppression. For example, clonal anergy can be induced in rats and mice fed high doses of MBP, or injected with MBP coupled to syngeneic spleen cells. In contrast, low doses of MBP, given orally, or preimmunization with MBP in incomplete adjuvant (which is nonencephalitogenic), gives rise to suppressor T cells that regulate EAE.

We, and others, have also demonstrated that suppressor T cells develop as Lewis rats spontaneously recover from EAE. These suppressor cells produce transforming growth factor β (TGF β), a cytokine that downregulates the secretion of inflammatory cytokines (i.e. IFN γ and lymphotoxin) by encephalitogenic T cells. Moreover, several studies have reported that EAE can be suppressed in rats and mice by treatment with TGF β . The disease has also been inhibited in rodents with interleukin 4 (IL-4) and IL-10, which are produced by the T_H2 subset of CD4⁺ T lymphocytes that provide T cell help for antibody-mediated immune responses. The suppressor T cells associated with recovery from EAE bear this pheno-

Table 2 T cell receptor usage and MHC class II restriction of encephalitogenic T cells

^bDominant epitope for Lewis rats.

^cExpressed by approximately 50% of responding T cells.

type, suggesting that suppression may reflect a switch from a T_H1 to a T_H2 response with a subsequent diversion from inflammatory T cells to helper T cell production.

However, it is likely that multiple mechanisms underlie the regulation of this autoimmune disease. For example, Pender and his colleagues have presented evidence that spontaneous recovery from EAE may also be due to the apoptotic elimination of encephalitogenic cells from the CNS, and others have reported that adrenal corticosteroids are involved in recovery. Recently, EAE has also been inhibited by treatment with antibodies against cytokines, adhesion molecules and chemokines. Thus, the autoimmune response can be modulated at many levels, from events associated with early T cell activation, to cytokine secretion by mature, activated effector cells.

Other therapeutic regimens are based on interfering with the antigen–MHC–TCR trimolecular complex that triggers the autoimmune response. These strategies have been directed against either the MHC class II molecules on the antigen-presenting cells, or the TCR of the encephalitogenic T cells. Success has been achieved by blocking MHC class II presentation of the encephalitogenic peptide using antibodies directed against MHC class II membrane antigens, and with TCR-specific antibodies which block presentation of the encephalitogenic epitope by the antigen-presenting cell. EAE can also be inhibited by immunizing animals with synthetic peptides corresponding to the CDR2 or CDR3 regions of the TCR expressed by the encephalitogenic T cells. Thus, Offner and Vandenbark were able to suppress EAE induced with the MBP 68–86 peptide by injecting Lewis rats with a peptide corresponding to V β 8.2 CDR2. Suppression is apparently due to an anti-idiotypic response directed against the V β 8.2 CDR2 region of the TCR. The ultimate objective of these various studies is to develop therapeutic measures that may eventually be suitable for the treatment of human demyelinating diseases.

Peripheral nerve disease

Experimental autoimmune encephalomyelitis is a

demyelinating disease of the CNS. In 1955, Waksman and Adams described an autoimmune disease of the peripheral nervous system, experimental autoimmune neuritis (EAN), which they induced in rabbits immunized with sciatic nerve tissue in adjuvant; EAN serves as a model for Guillain–Barré syndrome. Animals with EAN develop cellular immunity and antibodies to the P2 protein, an autoantigen found in peripheral nerve myelin. P2 is a basic protein containing 131 amino acid residues, which is structurally and antigenically distinct from the CNS MBP molecule. EAN has been transferred with CD4⁺ T cells from donors immunized with either P2 protein, or synthetic peptides corresponding to the P2 neuritogenic epitopes.

Investigations of EAE and EAN have provided insight into the mechanisms responsible for the induction of autoimmune tissue damage, and the regulation of immune responses directed against ‘self’ antigens. These studies will ultimately advance our understanding of mechanisms underlying human demyelinating diseases.

EXTRACELLULAR MATRIX

Adrian Shuttleworth, University of Manchester, Wellcome Trust Centre for Cell/Matrix Research, Manchester, UK

In recent years we have seen an explosion in information relating to all aspects of our understanding of the extracellular matrix (ECM). The major constituents identified in the ECM are collagens, proteoglycans and glycoproteins. At present 20 different collagens have been described which are capable of generating a variety of supramolecular structures. Considerable progress has been made in delineating the protein families found in the proteoglycans, and in understanding the role of alternative splicing that is a hallmark of many of the matrix glycoproteins. All cells respond to instructions from the outside, and we are beginning to understand not only the particular roles of individual macromolecules in the matrix, but also how the matrix binds and facilitates the action of growth factors. The dynamic nature of matrix belies earlier concepts that its only role was to act as a stable structural material, and while we understand more about the structural properties of some of the macromolecules, we are only just beginning to appreciate how macromolecules interact with one another and with cells, and indeed what signals are generated as a consequence of this cellular interaction.

The ECM evolved in response to forces acting on multicellular organisms; it provides mechanical support and physical strength to tissues, organs and to the whole organism. This may take the form of a simple basement membrane supporting cells in a multicellular organism like hydra, to the more diverse connective tissues, skin, tendon and ligament found in humans. The tendency to think of the matrix purely as providing strength and support belies the profound influences that it has on the behavior and pattern of gene expression of cells with which it is associated.

In humans the ECMs are highly varied in appearance, structure and function. This diversity provides tissue with rope-like characteristics such as tendon, the shock-absorbing characteristics of cartilage to the stony hardness of bone and the transparent matrix of cornea. Despite this tremendous variation in appearance, there is a great similarity in the types of molecules found in the ECM. It is the variation in the relative amounts of the different types of matrix macromolecules and the way that they are organized in the matrix that results in the varied appearances of connective tissues.

Cells of mesenchymal origin produce the ECM; these can be fibroblasts, smooth muscle cells or more differentiated cells, such as chondrocytes and osteoblasts. The matrix produced may be considered as a composite of insoluble fibers and soluble polymers. The principal fibers are collagen and elastin, while the soluble molecules include proteoglycans and glycoproteins.

Fibrous proteins – collagen and elastin

The collagens constitute what is now known to be a highly specialized family of glycoproteins. At present, 20 genetically distinct types encoded by at least 30 genes have been described. All collagens contain a domain with a triple helical conformation and are integral components of the extracellular matrix.

In triple helical domains three polypeptide (α) chains, each with a left-handed conformation, wind round each other to form a right-handed superhelix. Every third residue is glycine and of the repeating triplet [Gly-X-Y] that makes up the chain, approximately 20% of X and Y are imino acids, proline and hydroxyproline. This triple helical domain varies in length for the different collagen types and can either be continuous or interrupted with nonhelical domains.

The molecular configuration and tissue distribution of some of the collagens are shown in Table 1. Attempts have been made to classify collagens, both with regard to their gene organization and supramolecular structure, and while some of the more recently described collagens cannot be categorized in this way, it does provide a useful guide as to their role in the ECM.

The bulk of the collagen exists as fibrillar collagens, types I, II, III, V and XI. In these assemblies, molecules pack in quarter-staggered arrays to produce banded fibrils and fibers which provide mechanical support to the tissue (Figure 1). In contrast the FACIT (fibril associated collagens with interrupted triple helices), types IX, XII and XIV, are associated with the fibrillar collagens and may serve as a molecular link between fibrillar collagens and other matrix molecules. A different form of assembly is found in basement membranes, where type IV collagen forms a three-dimensional network (Figure 1). In addition beaded microfilaments are produced from type VI collagen (Figure 1), antiparallel dimers

Table 1 The collagen family

Collagen types	Number of α -	Supramolecular form	Distribution
I	2	Large diameter banded fibrils	Widespread: skin, tendon, cornea, bone
II	1	Small diameter banded fibrils	Cartilage, vitreous
III	1	Small diameter banded fibrils	Widespread in association with type I
IV	6	Network	Basement membranes
V	3	Heterotypic fibrils with type I and III	Widespread
VI	3	5 nm microfibrils with 100 nm periodicity	Widespread
VII	3	Anchoring fibrils	Specialized epithelia
VIII	2	Hexagonal lattice	Descemet's membrane
IX	3	FACIT	Cartilage, vitreous
X	1	Hexagonal lattice	Hypertrophic cartilage
XI	3	Heterotypic fibrils with type II	Cartilage
XII	1	FACIT	Widespread
XIII	1	Protein not isolated, 3 COL domains	Endothelial cells, epidermis
XIV	1	FACIT	Skin, tendon, cartilage
XV	1	Protein not isolated, 9 COL domains	Placenta, pancreas
XVI	1	FACIT	Skin, lung, amnion
XVII	1	Protein not isolated, 13 COL domains	Hemidesmosomes
XVIII	1	Protein not isolated, 10 COL domains	Liver
XIX	1	FACIT?	Unknown

of type VII collagen form anchoring fibrils, and the short-chain collagens VIII and X form hexagonal lattices.

While collagen undoubtedly provides the tensile strength of tissues, the variety of supramolecular forms found in the collagen family clearly indicate other roles for this important class of matrix macromolecules. In contrast, the other major fibrous protein in the ECM, elastin, is a single gene product and is largely responsible for the ability of tissues to stretch and recoil.

Elastin has a high degree of elasticity and can deform to large extensions with small forces; it is therefore found in abundance in those tissues that undergo repeated stretching, such as lung and blood vessels. Elastin (70 kDa) has a high content of hydrophobic amino acids and is the major protein of elastic fibers that form a randomly oriented, interconnected fiber system in many tissues. Elastin deposition in tissues is preceded by deposition of microfibrillar aggregates (10–12 nm); amorphous elastin deposits are seen to increase in these bundles until true elastic fibers are seen. The relative proportion of microfibril to elastin declines with age, and mature elastic fibers have a sparse association of microfibrillar material. The principal component of the microfibrils is the glycoprotein fibrillin. Defects in fibrillin on human chromosome 15 have been shown to result in the Marfan syndrome, a condition

where the failure to deposit elastin correctly can result in aortic dissection.

Proteoglycans

Proteoglycans are a diverse family of molecules that are characterized by having one or more glycosaminoglycan (GAG) chains attached to a protein core. These molecules are found inside cells, intercalated into membranes, and in the ECM, and appear to be ubiquitously associated with animal cells. Heterogeneity is found at both the protein level and particularly at the GAG level, where variations in both the type of GAG chain and the extent of modification are found.

Characteristically the GAG chain is composed of a repeat disaccharide sequence in which one sugar is an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine) and the other a uronic acid (galactose in one case). The main types of GAGs found in the matrix are shown in Table 2. As can be seen, the majority, chondroitin sulfate (CS), dermatan sulfate (DS), heparan sulfate (HS) and keratan sulfate (KS), are sulfated and are charged on each sugar residue, while hyaluronan (HA) is non-sulfated and charged only on alternate residues. In addition, hyaluronan is the only GAG chain that is not covalently attached to a protein core *in vivo*. The other GAG chains are attached to the protein core via a

Figure 1 Diagrammatic representation of type I (A), IV (B) and VI (C) collagen molecules and their supramolecular arrangements. Triple helical and globular portions not drawn to size. Variation in the size of the triple helical portion of the molecule, and the size and nature of the N- and C-terminal globular ends, determines to a large part the way in which individual monomers can aggregate. Type I collagen forms 67 nm cross-banded fibers/fibrils by quarter-staggered arrays of individual monomers. Type IV collagen forms a flexible open network by association through both the N- and C-terminal ends of the molecule. Type VI collagen with a short triple helix and large globular extensions allows lateral association of two antiparallel monomers and two of these dimers associate in a parallel fashion with their ends in register. End-to-end association of the tetramers forms 105 nm beaded microfibrils.

Table 2 Glycosaminoglycans

GAG	Repeat disaccharide	Mol. wt. (kDa)
Hyaluronic acid	Glucuronic acid and <i>N</i> -acetylglucosamine	5–10 000
Chondroitin sulfate	Glucuronic acid and <i>N</i> -acetylgalactosamine (can be sulfated at 4 or 6)	5–50
Dermatan sulfate	Glucuronic acid (or iduronic acid) and <i>N</i> -acetylgalactosamine (sulfated at 4 or 6)	10–60
Keratan sulfate	Galactose and <i>N</i> -acetylglucosamine (sulfated at 6)	5–20
Heparan sulfate	Glucuronic acid (or iduronic acid) and <i>N</i> -acetylglucosamine. Extensively sulfated on both residues	5–10

xylose residue linkage to a specific serine residue in the protein core, with the exception that KS chains are attached to proteins via *N*- and *O*-linked glycosidic linkages.

Hyaluronan is very large and can have a molecular weight of up to 10 000 kDa. It assumes a randomly kinked, coil structure which occupies a large solution volume and endows solutions with high viscosity. These molecules can self-associate and form networks; in addition, a number of proteoglycans can form supramolecular aggregates with HA. It therefore has an important role in the development and function of many tissues.

The advent of cloning and sequencing techniques has greatly increased the understanding of the protein core of proteoglycans and now a number of the protein cores can be classified into families on the basis of their domain structure. In the case of the small matrix proteoglycans (decorin, biglycan, fibromodulin) the characteristic features of the protein core are the leucine-rich repeats, the presence of which accounts for some of the protein-protein

interactions that these small proteoglycans exhibit. The large aggregating proteoglycans, aggrecan (found in cartilage) and versican (found in skin) also share similarities in the protein core, principal of which is the hyaluronate-binding region at the N-terminus. A similar domain is also found in the cell surface proteoglycan CD44.

The highly acidic and hydrophilic GAG chains might be expected to dominate the functional properties of these molecules, and while much of the tissue hydration caused by these molecules is attributable to this part of the molecule, specific interactions are mediated by both the GAG chains and the protein core. These include regulating protease activity, binding growth factors and mediating interactions with other matrix components.

Interactions and hydration of proteoglycans are key determinants of articular cartilage function, where the ability to withstand compressive forces serves to protect the underlying bone. In cartilage, proteoglycans, such as aggrecan, form a supra-molecular aggregate with hyaluronan and this interaction is stabilized by link protein (Figure 2). This helps maintain a high concentration of proteoglycans in cartilage, which is important in determining the hydration of the tissue. Collagen fibers provide the scaffold that resists tensile forces, while the proteoglycan aggregates provide a hydrated, viscous gel that absorbs compressive forces.

Glycoproteins

The collagen family of proteins contain a triple helical portion in their structure, and the proteoglycans

all contain GAG chains attached to a protein core. Matrix glycoproteins, however, apart from containing O-linked and/or N-linked sugars, appear to have little in common with one another. Functionally, the ability to interact with other matrix molecules and with cells appears to be the common feature of this class of molecule, and a number have been described as 'adhesive glycoproteins'.

Many of the matrix glycoproteins contain distinct and functionally active protein domains that prescribe interactions with the cell surface as well as other matrix molecules. In addition, a number of the molecules form oligomers, and families of molecules are produced by alternative splicing. Many possess short aspartate-containing sequences such as RGD, which mediate cellular adhesion through the integrin family of membrane receptors.

Fibronectin is found in the ECM and blood plasma; it contains two nonidentical subunits joined by disulfide bonds and is the best characterized of the adhesive glycoproteins. The domain structure of one of the subunits is shown in Figure 3, and different domains are specialized for binding extracellular matrix molecules of bacterial or eukaryotic membrane receptors. Different fibronectin isoforms arise by alternative splicing of the transcript of a single gene. Its principal functions appear to be in cellular migration during development and wound healing, regulation of cell growth and differentiation, and hemostasis and thrombosis.

Many mesenchymal cells preferentially use fibronectin to adhere to; in contrast epithelial and endothelial cells use the glycoprotein laminin. Laminins are present in all basement membranes and have

Figure 2 Aggrecan organization in cartilage. In cartilage the large proteoglycan aggrecan interacts with the GAG hyaluronan, this association is stabilized by the glycoprotein link protein. The aggrecan aggregate may have a molecular weight approaching 1 million kDa.

Figure 3 Domain structure of one of the subunits of fibronectin. FN type I repeats (□), FN type II repeats (■) and the FN type III repeats (▨) are shown. The three type III repeats that undergo alternative splicing are indicated. The number of additional amino acids (aa) encoded by splice variants of the third FN type III segment are indicated.

major influences on adhesion, growth, migration and differentiation of cells. Laminins are composed of three chains (α , β and γ) with molecular weights of 140–400 kDa. At present eight genetically distinct laminin chains and seven different assemblies are known. Chain association occurs through an α -helical coiled coil near the C-terminus of each chain. The specific binding of laminins to perlecan, entactin, type IV collagen and other basement membrane components suggests that laminins play a crucial role in the supramolecular organization and assembly of basement membranes.

The type III repeat of fibronectin containing the RGDS cell-binding motif is found in a number of matrix glycoproteins, including thrombospondin and tenascin, and is probably a recurring motif for cell binding. Another common domain in matrix glycoproteins is the epidermal growth factor (EGF) repeat. In addition to laminin, entactin, thrombospondin and tenascin, it is found in the proteoglycans aggrecan and versican. These repeats may mediate two functions: first, facilitate protein–protein interactions; and second, interact with EGF receptors and control cellular activity. The occurrence of multiple domains in the glycoproteins suggests multiple functions, and during evolution this has been achieved by exon shuffling, which has produced the variety of matrix glycoproteins.

Matrix turnover

In most adult tissues turnover of matrix is slow. There are, however, situations such as in embryonic and postnatal development, and in the postpartum uterus, where there is considerable tissue removal and replacement. The structural fibers, in general,

have a longer half-life than the ground substance. In the case of elastin in aorta it has been suggested that, under normal circumstances, once laid down it lasts through life.

Resorption of matrix components is achieved by resident cells as well as infiltrating cells, such as neutrophils and macrophages. In general both extracellular and intracellular mechanisms are thought to play a part, although current thinking is that the initial step is an extracellular proteolytic cleavage.

Matrix macromolecules can be degraded by four classes of proteinases, and their relative roles *in vivo* may vary depending on the situation. The cysteine and aspartic proteinases function optimally at acid pH, and while there may be local acidic environments and some of the cysteine proteinases have been found extracellularly, they are probably major determinants of degradation of phagocytosed material. Circulating plasminogen activator and plasmin are key serine proteinases in regulation of turnover. The elastase and cathepsin G of polymorphonuclear leukocytes and the tryptase and chymase of mast cells, are all serine proteinases capable of matrix degradation.

The matrix metalloproteinases (MMPs) are a family of enzymes which bind metals, are secreted in an inactive form and require extracellular activation. There are at least nine members of the MMP gene family, which share extensive sequence homology, but differ in their substrate specificity (Table 3). Regulation of activity is determined intracellularly by transcriptional control, and extracellularly by activation and the presence of specific inhibitors. Inhibitors like α_2 -macroglobulin bind and trap active enzymes; the tissue inhibitors of metalloproteinases (TIMPs) form noncovalent complexes with active

Table 3 Matrix metalloproteinase family

A number of other members of the family have been described and recent work shows the presence of a membrane-bound matrix metalloproteinase on some tumor cells.

forms of MMPs and in some cases with the latent enzymes. TIMP-1 and TIMP-2 have been described and there may be other members of this family.

Cell matrix receptors

Cells respond to their environment. This can be seen in a variety of morphogenetic effects, cell attachment, spreading, differentiation, etc., and in recent years it has become increasingly apparent that the ECM can regulate the expression of a variety of genes which control cellular activity. These effects are mediated by a variety of cell surface receptors, including integrins, proteoglycans and selectins.

Integrins, a family of cell surface heterodimers, are receptors for a number of matrix molecules. While there are about 14 α and 8 β subunits, only about 20 different dimer combinations have been identified. Ligands appear to bind to multiple integrins, and individual integrin receptors appear to bind many different ligands, indicating that redundancy may be a key feature of this type of interaction. Movement and shape changes seen in cells indicate that integrins associate with intracellular cytoskeletal elements. Ligand binding to integrins may also involve signal transduction and gene regulation. This, coupled with the presence of growth factor receptors, provides a mechanism for cellular response to changing matrix conditions.

EYE, AUTOIMMUNE DISEASE

Rachel R Caspi, Laboratory of Immunology, NEI, National Institutes of Health, Bethesda, Maryland, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The eye is subject to a number of sight-threatening inflammatory disorders of an immune-mediated nature that can affect different parts of the ocular anatomy. The uveitic entities affecting the back of the eye are particularly likely to affect vision adversely, and, in fact, blindness is a not infrequent outcome. Some uveitic diseases in humans are disorders confined only to the eye, whereas others are part of a more generalized, systemic, syndrome. Because the eye is an immunologically privileged organ, special considerations apply to the establishment and maintenance, as well as the potential breakdown, of self-tolerance to eye-specific components. Animal models of ocular autoimmunity induced with eye-derived antigens are being used to study these questions, and are providing valuable insights into the basic mechanisms of, and potential immunotherapeutic approaches to, immunologically mediated eye disease.

Autoimmune and immune-mediated eye diseases in humans

Although strong associations have been noted between many uveitic diseases and HLA type, indicating an immunogenetic component to disease etiology, the extent to which autoimmunity in the strict sense plays a role in human disease is still controversial. The reason for this is that in most cases the eliciting antigens have not yet been positively identified. One exception is phacoanaphylaxis, caused by an autoimmune response to lens proteins, usually following trauma and disruption of the lens capsule. Lens-specific antibodies and complement activation appear to be intimately involved in the disorder, but it is still unknown whether a significant cell-mediated component exists. In animal models of lens-induced uveitis (LIU), a primarily humoral mechanism of disease has been demonstrated.

In posterior uveitic disease, sympathetic ophthalmia (SO) has for a long time been considered the prototypic ocular autoimmune disease. As in phacoanaphylaxis, pathogenesis can be linked to a discrete inducing event, i.e. a penetrating trauma to one eye. Characteristic of SO is the subsequent development, weeks to months later, of an acute inflammation in the contralateral (sympathizing) eye, which has not been injured. This has been attributed to the development of an autoimmune response to

the ocular antigens released into the bloodstream from the injured (exciting) eye. It is unclear why SO develops in only a small proportion of the cases of ocular trauma, and what the predisposing factors are. Genetic susceptibility and a concomitant adjuvant effect due to infection have been proposed as possible facilitating mechanisms. Additional posterior and intermediate uveitic diseases for which an autoimmune component(s) has been postulated include birdshot retinochoroidopathy, and systemic diseases with ocular involvement, such as Behçet's disease and Vogt-Koyanagi-Harada syndrome. Many patients suffering from these diseases display strong immunologic responses to retinal proteins. Of particular note, a number of studies that demonstrated specific antibody and lymphocyte responses to the retinal soluble antigen (S-Ag) in birdshot retinochoroidopathy patients and in other uveitis patients. Although it is difficult to determine to what extent these responses might play a role in the etiology and/or pathogenesis of their disease, the S-Ag is one of several retinal proteins which cause experimental autoimmune uveoretinitis in laboratory animals (see below). Antigens that might be involved in anterior uveitic disease affecting the iris and ciliary body are also yet to be identified, but at least one type of anterior uveitis (the Reiter syndrome) has been linked to the presence of anti-*Klebsiella* responses in the affected patients (see below).

Animal models of uveitis, elicited by immunization with eye-derived proteins, have been developed and serve as research tools that have yielded invaluable insights into the mechanisms and therapy of these sight-threatening ocular inflammatory diseases (Table 1).

Is there tolerance to ocular antigens?

Central to the understanding of the mechanisms of ocular autoimmunity is the special localization of the ocular antigens in relation to the immune system. It has long been known that the eye is an 'immunologically privileged' organ, such that histoincompatible tissue grafts placed in the anterior chamber of the eye are not rejected. The reason for this immune privilege has been attributed mainly to the fact that there is no lymphatic drainage of the interior of the globe, and to the existence of a blood-ocular barrier

Table 1 Animal models of autoimmune diseases affecting the eye

<i>Model</i>	<i>Animal species</i>	<i>Main site of inflammation</i>	<i>Eliciting antigen(s)</i>	<i>Primary immunologic mechanism</i>	<i>Human disease(s) represented</i>
Lens-induced uveitis (LIU)	Rat, rabbit, guinea pig	Panuveitis	Lens proteins	Humoral	Phacoanaphylaxis
Experimental autoimmune anterior uveitis (EAAU)*	Rat	Anterior (iris and ciliary body)	Melanin proteins	Cell mediated	Anterior uveitis
Experimental autoimmune uveoretinitis (EAU)	Mouse, rat, guinea pig, rabbit, monkey	Posterior (retina and choroid)	Photoreceptor proteins	Cell mediated	Intermediate and posterior uveitis (sympathetic ophthalmia, birdshot retinochoroidopathy, and others)

*Also known as melanin protein-induced uveitis (EMIU).

which prevents free egress of lymphocytes from the circulation into the ocular tissues.

Current knowledge postulates that most lymphocytes capable of recognizing tissue-specific antigens are eliminated by negative selection in the thymus during ontogeny. Those that escape deletion must be controlled in the periphery by other tolerance-inducing mechanisms, such as clonal anergy or deletion due to encounter with tissue-specific antigen in the absence of accessory signals, or active suppression by regulatory cells. It is unclear, however, to what extent any of these mechanisms are operative in the case of ocular antigens. The separation between the immune system and the eye occurs early in ontogeny, and although recent work shows that messenger RNA encoding some retinal antigens can be detected in the thymus by the sensitive method of polymerase chain reaction (PCR), detectable levels of retinal proteins are not readily demonstrable in the thymus. Antibodies and lymphocytes that recognize ocular antigens are detectable in the blood of healthy human and animal subjects who show no evidence of autoimmunity. This supports the notion that there is neither clonal deletion nor inactivation of these cells. Disruption of the blood-retinal barrier during trauma or inflammation can give access to lymphocytes, which are not tolerant, into the eye. Antigen may be presented either locally (major histocompatibility complex (MHC) class II-expressing cells are present in the inflamed eye) or peripherally (antigen which escapes under the conjunctiva will be drained into regional lymph nodes). How, then, is ocular nonaggression maintained? And what are the circumstances leading to its breakdown, resulting in autoimmune uveitis?

Insights gained from animal models of ocular autoimmunity

The questions outlined above are being studied in animal models of ocular autoimmunity (Table 1). The best studied is experimental autoimmune uveoretinitis (EAU), which serves as a model for human posterior uveitic disease that is most likely to result in impairment of vision. EAU can be induced in various species of rodents and in primates by any of several defined retinal antigens injected in emulsion with complete Freund's adjuvant (CFA). A number of uveitogenic proteins derived from the photoreceptor cell layer have been identified (Table 2). EAU is characterized by destruction of the photoreceptor cells of the retina, where the eliciting antigen(s) are located (Figure 1), and is usually accompanied by autoimmune inflammation of the pineal gland ('third eye'), which shares ocular-specific antigens with the retina.

A dictum which clearly emerges from studies in animal models is that mere exposure to an ocular antigen is insufficient to elicit ocular autoimmunity. Use of adjuvants is mandatory to elicit uveitis in experimental animals, and a concomitant microbial infection has been implicated in cases of SO in humans. Bacterial components and toxins are particularly efficient in promoting induction of EAU, possibly because of their effects in promoting a T_H1 -type response to the uveitogen. Depending on the species, the adjuvant effect can be provided by mycobacterial components (CFA), and/or by products of gram-negative bacteria such as *Bordetella pertussis* toxin or *Klebsiella pneumoniae* capsular lipopolysaccharide. Some studies indicate that microbial

Table 2 Uveitogenic photoreceptor-derived proteins

Protein	Mol. wt. (kDa)	Biological function	Location
Retinal soluble antigen (S-Ag, arrestin)	48	Phototransduction cascade	Intracellular
Interphotoreceptor retinoid-binding protein (IRBP)	140	Transport of vitamin A derivatives between the photoreceptor and the retinal pigment epithelium	Extracellular
Rhodopsin (and its illuminated form, opsin)	40	Rod visual pigment	Intracellular
Recoverin	40	Calcium-binding protein	Intracellular
Phosducin	33	Phosphoprotein	Intracellular

components may do more than simply provide an adjuvant effect. Sequence similarities have been found between a uveitopathogenic site of S-Ag, *Escherichia coli* protein and yeast histone C3. Moreover, rats immunized with synthetic peptides containing these microbial sequences develop typical EAU and demonstrate lymphocyte responses cross-reactive with the corresponding peptide sequence derived from S-Ag. These findings suggest that under some circumstances molecular mimicry might play a role in induction of ocular autoimmunity. In this context, of note are the reports that, in human anterior uveitis associated with rheumatoid disease and HLA-B27, a gram-negative bacterial infection precedes the onset of symptoms. A homology of six amino acids was found between HLA-B27 and *K. pneumoniae* nitrogenase, with antibodies against this residue being found in a high proportion of the patients.

A central role for T cells in human uveitis is indicated by the dramatic response of some of these diseases to the T cell targeting agent cyclosporine. The immunopathogenic mechanisms of EAU, as studied in both rats and mice, indicate a central involvement of T lymphocytes in this experimental disorder. Thus, EAU can be adoptively transferred with long-term T cell lines and clones, and is suppressed by therapy that targets T cells, including cyclosporine, monoclonal antibodies to T cell markers, and interleukin 2 (IL-2) receptor targeting therapy with monoclonal antibodies and chimeric toxins. A number of uveitogenic epitopes for rats and mice have now been elucidated, and research aimed at characterizing the T cell receptors of uveitogenic cells is under way. Analyses of the lymphokine profile of uveitogenic T cell lines and clones have uniformly indicated that the pathogenic lymphocyte produces high levels of the lymphokine interferon γ (IFN γ), or in some cases both IFN γ and IL-4, characteristic of a T_H1-type or a T_H0-type cell. In contrast, some types of protective responses (e.g. tolerance induced by oral administration of antigen) are characterized by a concomitant induction of IL-10, IL-4 and trans-

forming growth factor β (TGF β), suggesting that the putative regulatory lymphocyte may be of the T_H2 phenotype. Thus, immunotherapy designed to direct an ongoing autoimmune response towards the T_H2 differentiation pathway could potentially divert the response from a pathogenic to a nonpathogenic one. This basic research may eventually lead to the development of novel therapeutic strategies, targeting the specific lymphocytes and processes involved in ocular autoimmunity.

Similarly to human uveitis, EAU shows a strong genetic association. In the mouse EAU model, immunogenetic studies done in congenic strains indicate that susceptibility is connected to the MHC haplotype, presumably due to recognition of the appropriate (pathogenic) epitopes. However, quantitative aspects of the disease are strongly modulated by background, non-MHC genes, whose effects can be sufficiently strong to render the bearer of a 'susceptible' MHC haplotype resistant to disease. The mechanisms for most of these genetic effects remain obscure, but at least one is connected to a propensity to mount a T_H1-dominated immune response. The susceptible genetic background in both rats (Lewis) and mice (C57/BL) is one that supports development of an IFN γ -dominated response to the uveitogen, whereas resistant strains tend to mount an IFN γ -low (but not necessarily an IL-4-high, i.e. T_H2-dominated) response. Thus, while susceptibility may depend on a dominant T_H1 response, it appears that resistance may be achieved through more than one regulatory pathway. It is unclear at this time whether these findings have a parallel in genetic susceptibility and resistance to ocular autoimmunity in humans.

Although a number of studies in the EAU model have indicated a role for regulatory (T_H2-type?) cells in downregulation of disease, it is still an open question whether such regulatory cells exist before the onset of ocular autoimmunity and have a role in its prevention. It was believed in the past that because the immune system never comes in contact with ocular antigens, development of such active regulation is both unlikely and unnecessary. It is clear

Figure 1 Histopathology of experimental and clinical uveitis. (A). Section through a healthy mouse eye. Note ordered structure of tissue layers and absence of inflammation. V: vitreous body; G: ganglion cell layer (cell bodies and nuclei); P: photoreceptor cell layer (nuclei and outer segments); rpe: retinal pigment epithelium; c: choroid; s: sclera. b: retinal blood vessel. (B). Section through a mouse eye with experimental autoimmune uveitis induced with IRBP. Note disrupted ocular architecture: cells and debris in the vitreous, vasculitis, retinal folds and retinal detachment, subretinal hemorrhage, subretinal granuloma, disrupted retinal pigment epithelium, infiltrated and thickened choroid. (C). Section through a human eye with uveitic disease. This patient has ocular sarcoid. Note similarity in histological appearance to experimental uveitis in the mouse.

today that this view is no longer tenable. Recent work has shown that by using the sensitive PCR technique, messenger RNA for ocular antigens is detectable in the thymus. The proteins themselves, however, are not readily detectable by conventional laboratory techniques and it is not clear whether their level of expression (if indeed they are expressed) is sufficient to contribute to induction of tolerance. However, easily detectable levels of uveitogenic proteins such as S-Ag and interphotoreceptor retinoid-binding protein (IRBP) are present in the pineal gland (third eye), which has no blood–organ barrier. Furthermore, numerous studies indicated that antigens placed in the anterior chamber of the eye (AC) do reach and are recognized by the immune system. In some cases (depending on the antigen), a deviant form of immunity is elicited, appropriately known as anterior chamber-associated immune deviation (ACAID). ACAID is characterized by suppressed delayed-type hypersensitivity responses, together with normal, or supernormal, induction of cytotoxic T lymphocytes and (noncomplement-binding) antibodies. Some researchers suggest that ocular antigens escaping from the AC into the circulation through the trabecular meshwork (facilitated by inflammation?) may naturally elicit an ACAID-like response, which would prevent, rather than promote, induction of uveitis. Under experimental conditions, ACAID induced to a uveitogenic retinal antigen can protect mice and rats from EAU induced by a subsequent immunization with the same antigen. It is unclear, however, whether a natural equivalent of this experimental phenomenon exists and plays a role in preventing ocular autoimmune disease.

Irrespective of the existence of putative systemic protective responses, the eye has several locally acting mechanisms that might help to curb autoimmune responses if and when the integrity of the blood–retinal barrier is breached. These mechanisms are also believed to contribute to ocular immune privilege. The ocular fluids contain immunosuppressive factors and cytokines, among them various neuropeptides and TGF β . More recently, high levels of Fas ligand were identified in ocular tissues. Lymphocytes infiltrating the AC underwent a Fas-mediated programmed cell death by apoptosis, and were prevented from causing tissue damage. In addition, ocular resident cells are able to suppress activation and clonal expansion of uveitogenic T cells through what is apparently a Fas-unrelated mechanism. For example, retinal glial cells (Müller cells) and ciliary body cells were shown to suppress activation and clonal expansion of uveitogenic T lymphocytes in an *in vitro* system derived from the rat EAU model, and chemical depletion of retinal Müller cells caused a

normally EAU-resistant rat strain to develop disease. Interestingly, the potent lymphocyte inhibitory function of these ocular resident cells was found to mask an underlying capacity to act as antigen-presenting cells. It is an intriguing notion that locally acting suppression mechanisms of this type might have evolved to prevent organ-resident cells, with the potential to present autoantigens, from initiating and perpetuating autoimmunity.

In summary, currently available evidence points to the notion that central mechanisms involving the thymus may have a limited role in maintaining a state of functional tolerance to ocular antigens. That ocular autoimmunity is the exception, rather than the rule, may be attributable to the effectiveness of the blood-ocular barrier and the various local and peripheral immunosuppressive mechanisms in curtailing immunologic processes that would lead to ocular autoimmune disease.

EYE INFECTIONS

Marjorie Anne Monnickendam, PHLS Communicable Disease Surveillance Centre, London, UK

Strategies of infection and host defense mechanisms

Pathogens reach the eye by two routes. They infect the eye directly through the conjunctiva and cornea, or they reach the eye through the vascular, lymphatic or nervous systems following infection elsewhere. The front of the eye protects itself from infection in many ways, and few organisms can infect the intact front surface. An eye with a damaged front surface is, however, far more susceptible to infection. Pathogens which reach the avascular tissues of the eye are partially isolated from host defense mechanisms. They can multiply more quickly and cause far more damage in these tissues than in vascularized tissue. Infection of the eye can compromise vision and lead to blindness. The common ocular pathogens can be

divided into two groups according to whether they cause short-term or long-term infections.

Short-term infections

Viruses are the commonest causes of short-term infections and they infect the eye directly. It seems likely that host immune responses terminate infection. These infections do not usually cause long-term damage to the eye.

Picornaviruses cause acute hemorrhagic conjunctivitis, which is common in tropical and subtropical areas of the world with high humidity and high population densities. There have been two pandemics. Enterovirus 70 is the commonest cause, but coxsackie virus A24, poliovirus and adenoviruses are also associated with this disease.

Adenoviruses cause acute conjunctivitis and epidemic keratoconjunctivitis. They are the commonest cause of ocular infection in developed countries. Many adenovirus types have been isolated from the eyes of patients, and types 3, 7 and 10 predominate in the UK. Adenoviruses also cause ocular disease in developing countries: they have been isolated from patients with acute hemorrhagic conjunctivitis (see above) and they were the commonest cause of acute conjunctivitis in a study in Pakistan, where virtually all the isolates were type 8.

Ocular infection with enteroviruses and adenoviruses evokes the production of specific antibodies. Antibodies against enteroviruses can neutralize virus infectivity, and antibodies against adenoviruses can fix complement. The roles of these antibodies in disease are not known.

Measles virus affects the conjunctiva and cornea of most, if not all patients with measles. This usually resolves without damage to the eye. In parts of Africa, however, many children with measles subsequently develop corneal ulceration and postmeasles blindness. Although the roles of immune responses in measles are well defined, their importance in the development of postmeasles blindness is not known. Measles infection can reduce tear flow, and children who are severely ill are unable to close their eyelids, so that their eyes become more susceptible to secondary infection. Malnutrition and measles virus infection both cause immunosuppression. Vitamin A deficiency can lead to xerophthalmia, and traditional eye medicines can damage the eye. In some areas of Africa, children with measles often develop corneal ulcers caused by herpes simplex virus. This may result from direct infection of the eye or from reactivation of existing infection (see below).

Long-term infections

Ocular pathogens establish long-term infections by direct infection of the eye or indirectly following dissemination of infection from elsewhere in the host. These pathogens survive or evade the host immune response, damage the eye and affect sight.

Herpes simplex virus

Herpes simplex virus type 1 (HSV-1) is associated with a range of eye diseases known as herpes simplex virus ophthalmia (HSVO). It causes conjunctivitis and lesions in the skin surrounding the eye, and ophthalmologists commonly describe this as primary HSVO. It also causes corneal ulceration, vascularization of the cornea, uveitis and glaucoma, and consequent loss of vision. Ophthalmologists describe this as recurrent HSVO. Studies of patients with HSVO

have shown that the terms primary and recurrent are inaccurate and misleading. It has therefore been proposed that HSVO should be described by its clinical features.

A life-long infection is established by HSV-1 in the sensory ganglia where it remains isolated from the host immune system. Occasional forays along nerves to the eye produce active HSVO, and HSV-1 can be isolated from the eyes for about a week. This suggests that host defense mechanisms terminate the active phase. Active corneal disease can however last for months; HSV-1 can survive for long periods in the cornea and has been isolated from corneas during quiescence. Patients with HSVO develop humoral and cellular immune responses to HSV.

Experimental infections in animals have shown that different clinical forms of HSVO result from differences in genetic factors of host animals and also differences between strains of HSV-1. The ability of HSV-1 to cause severe corneal disease, to establish latent infection in the eye and to multiply in isolated trigeminal ganglia infected *in vitro* differs in different strains of mice. Susceptibility to corneal disease is determined by alleles of the immunoglobulin heavy chain locus. Paradoxically, the major functional immunological difference is that susceptible mice have a much higher proportion of T helper lymphocytes in the corneal periphery than resistant mice. Different strains of HSV-1 produce different forms of HSVO. Strains isolated from patients with conjunctivitis caused conjunctivitis and strains from patients with corneal disease caused corneal disease. Strains isolated from patients with chronic stromal disease produced larger amounts of soluble precursor glycoprotein D than strains isolated from patients with other forms of HSVO.

Studies in rabbits and mice showed that previous ocular or dermal infection, immunization with inactivated virus, subunit vaccines and human hyperimmune gamma globulin all conferred a degree of protective immunity against subsequent ocular infection. Immunization of mice with HSV glycoprotein D prevented the development of stromal keratitis and corneal vascularization, and spread of infection to the trigeminal ganglia and the central nervous system. These protective effects were associated with raised levels of neutralizing antibodies and complement-dependent cytotoxicity.

Trachoma

Chlamydia trachomatis is an obligate intracellular bacterium which infects mucosal epithelia. Serovars A, B, Ba and C cause trachoma, an important cause of preventable blindness in developing countries. Infection is transmitted directly from eye to eye. In

contrast, serovars D to K are a common cause of genital infection in developed countries and occasionally infect eyes, but they do not cause trachoma.

Patients with trachoma have immune responses to the agent. Tears and blood contain antibodies which reduce the infectivity of *C. trachomatis*. Skin-testing for cell-mediated responses produced negative results in children with trachoma in The Gambia, but adults with severe trachoma in South Africa had positive reactions. Immunohistochemical studies of conjunctival biopsies obtained from patients with trachoma show that the inflammatory cell infiltrate contains B and T lymphocytes and that epithelial cells have MHC class II antigens (HLA-DR) as well as class I on their surfaces.

When strains of *C. trachomatis* isolated from patients with trachoma were inoculated into the eyes of blind human volunteers and nonhuman primates, they did not produce trachoma. They produced disease resembling that found in developed countries. Studies in animals (subhuman primates infected with *C. trachomatis*; guinea pigs infected with guinea pig inclusion conjunctivitis agent, a strain of *C. psittaci*) showed that antibodies and cell-mediated responses developed during infection and terminated infection. Features of trachoma, i.e. chronic conjunctivitis, corneal vascularization, scarring of the palpebral conjunctivae and subsequent distortion of the eye-lids developed after repeated episodes of infection. In guinea pigs, repeated ocular infection produced partial microbiological immunity which comprised two components. The short-term local component increased the amount of agent required to initiate reinfection and was probably mediated by secretory IgA in the eye. The long-term systemic component limited the growth of the agent following reinfection and was probably mediated by T lymphocytes. It paralleled the delayed-type hypersensitivity skin reaction to the agent, was associated with tissue damage and was suppressed by cyclosporine.

Staphylococcal eye diseases

Staphylococcus aureus causes acute and chronic conjunctivitis, corneal ulcers and blepharitis. Patients with staphylococcal eye diseases were skin-tested with staphylococcal antigens to see if hypersensitivity reactions played a role in the disease process. Patients with corneal disease were more likely to have enhanced delayed-type skin responses to killed whole cells of *S. aureus* and *S. epidermidis* than those with blepharitis. Experimental infections in rabbits have demonstrated that immune responses contribute to pathology. Ocular infection only produced

corneal disease and blepharitis when it was preceded by immunization with staphylococcal antigens.

Leprosy

Mycobacterium leprae causes leprosy, which is common in many developing countries. It is divided into four clinical forms. Patients with lepromatous leprosy have disseminated infection associated with poor cellular immune responses. They often develop major ocular complications and blindness. The mechanisms which protect the front surface of the eye are compromised because of damage to the facial and trigeminal nerves caused by *M. leprae*. This leads to lid abnormalities and abolition of the blink and corneal reflexes, which render the eye more susceptible to secondary infection. The iris is damaged by acute and chronic iritis. Acute iritis is part of a generalized reaction, known as the 'lepra' reaction, which is caused by the deposition of immune complexes in the iris. Acute iritis is similar to other forms of acute nonleptous iritis, and can lead to glaucoma and cataract. Chronic iritis is caused by *M. leprae* growing in the iris, causing iris atrophy. This is the commonest cause of visual impairment.

Onchocerciasis

Onchocerciasis or river blindness is caused by the filarial nematode *Onchocerca volvulus*, which is transmitted by several species of blackflies of the genus *Simulium*. Infected blackflies transmit larvae to humans by biting them. Larvae migrate to subcutaneous tissues where they become mature adults. Gravid females produce large numbers of microfilariae which migrate throughout the body. Over a period of many years, microfilariae migrate into the ocular tissues and die, causing small inflammatory lesions which leave scars. The accumulation of small scars in the cornea and the retina cause blindness. Live microfilariae are difficult to see in the cornea because they do not stimulate an inflammatory response. In contrast, dead microfilariae evoke punctate keratitis; small lesions which consist of dead microfilariae surrounded by lymphocytes, eosinophils and local edema.

Drugs which kill microfilariae cause a marked inflammatory response known as the 'Mazotti reaction' and concurrent treatment with anti-inflammatory drugs is required to reduce the severity of this reaction. The drugs suramin and diethylcarbamazine cause severe reactions, increasing corneal and retinal lesions and damaging the optic nerve, causing blindness. Ivermectin is currently being tested on patients and it has significant advantages over the other two drugs. In clinical trials, the number of microfilariae in the anterior chamber of the eye was reduced,

patients had the same or improved visual acuity and the Mazotti reaction was less marked. Ivermectin does not enter the eye, so that ocular tissues are spared the damaging and potentially blinding reaction to dead microfilariae.

F

FAS (CD95) AND FAS LIGAND

Mark R Alderson, Department of Immunology, Corixa Corporation, Seattle, Washington, USA

David H Lynch, Department of Immunobiology, Immunex Corporation, Seattle, Washington, USA

Apoptotic elimination of cells is an important mechanism for both homeostatic regulation of the immune system and ensuring that autoreactive and unwanted lymphocytes are removed. One means of achieving this control is mediated via the cognate

interactions between Fas (APO-1/CD95) and Fas ligand (FasL). FasL binds to its receptor and in many instances this results in a cascade of events leading to the death of the target cell within hours. The prime role of the Fas/FasL apoptotic pathway

appears to be in peripheral deletion of autoreactive lymphocytes and limiting the extent of an immune response by clonal downsizing. Dysregulation of the Fas/FasL apoptotic pathway may contribute to certain disease states, including autoimmune disorders, tumor progression and immunodeficiency.

Fas

Fas was independently identified by two laboratories using monoclonal antibodies (anti-Fas and anti-APO-1) to a cell surface molecule that induced apoptosis in certain cell lines. The subsequent cloning of Fas demonstrated it to be a member of the tumor necrosis factor (TNF) receptor (TNF-R) family of membrane proteins. This receptor family includes the two TNF-Rs (p55 and p75), CD27, CD30, CD40, 4-1BB, OX-40, LT β R, human DR3 (death receptor 3)/WSL-1 and DR-4 (TRAIL receptor), human HVEM (herpesvirus entry mediator), and chicken CAR1 (receptor for cytopathic avian leukosis-sarcoma viruses). Members of this family of receptors share 20–25% amino acid identity and contain varying numbers of cysteine-rich extracellular domains. Cloning and mapping studies revealed that the *lpr* (lymphoproliferation) mouse mutation, which manifests itself as hypergammaglobulinemia, autoantibody production and the accumulation of CD3⁺CD4⁺CD8[−] lymphocytes in secondary lymphoid tissues, is a recessive mutation in Fas. The predominant function of Fas is to transduce apoptotic signals and Fas shares a homologous 70 amino acid 'death domain' sequence in its cytoplasmic region with the p55 TNF-R and with the more recently identified apoptotic receptors DR-3/WSL-1, DR-4 and CAR1. The death domain is distantly related to the *Drosophila* suicide gene reaper and is essential for transducing apoptotic signals. Fas is expressed by many cell types in the immune system but simple expression of Fas does not correlate well with susceptibility to Fas-mediated apoptosis. Whether a cell will undergo apoptosis upon ligation of Fas appears to be primarily dependent upon the activation state of the cell and by other signals that the cell has received that regulate apoptosis in a positive or negative manner (discussed further below).

Fas ligand (FasL)

The structure of Fas and its homology with the other members of the TNF-R family suggested that it was a receptor for an unknown cytokine. FasL was first identified using a bioassay that demonstrated that a CD8⁺ cytotoxic T lymphocyte (CTL) hybridoma cell line could induce lysis of Fas⁺ but not Fas[−] target

cells. The cDNA for FasL was subsequently cloned and shown to encode a type II transmembrane protein (i.e. its C-terminus is extracellular) of approximately 40 kDa that is part of the TNF family of ligands. The TNF ligand family includes TNF, LT α , LT β , CD27L, CD30L, CD40L, 4-1BBL, OX40L and TRAIL (TNF-related apoptosis-inducing ligand). Mice that are homozygous for the *gld* (generalized lymphoproliferative disease) mutation have an autoimmune phenotype virtually identical to that of mice homozygous for the *lpr* (Fas) mutation. Studies have demonstrated that this disease process is the result of a point mutation in the gene encoding FasL. FasL forms homotrimers of subunits that complement the trimeric receptor complex structure. FasL is expressed by both CD4⁺ and CD8⁺ T cells, and is predominantly expressed by the T_H1 subset of CD4⁺ T cells. FasL has also been reported to be expressed by neutrophils and human immunodeficiency virus (HIV)-infected or CD4 cross-linked macrophages and certain tumors and immune-privileged tissues (see below). Like TNF, membrane FasL is cleaved by a metalloprotease into a soluble form that is biologically active and thus can mediate its effect both locally and systemically.

Table 1 lists the expression and functions of Fas/FasL.

Fas apoptosis signaling pathway

The mechanism by which ligation of Fas on a cell surface leads to apoptosis is an area of current

Table 1 Expression and function of Fas/FasL

	FasL	Fas	Biological function
Naive T cells	−	±	Activation
Activated T cells	+	+	Apoptosis (AICD)
NK cells	+	−	Target cell apoptosis
slg activated B cells	−	+	Activation
CD40L activated B cells	−	+	Apoptosis
Self reactive (anergic) B cells	−	+	Apoptosis
Neutrophils	+	+	Apoptosis
Eosinophils	−	+	?
Monocytes	−	+	?
Activated macrophages	±	+	Apoptosis
Retina/cornea	+	−	Immune privilege
Sertoli cells (testes)	+	−	Immune privilege
Hepatocytes	−	+	Apoptosis/hepatitis
Normal thyrocytes	+	−	Immune privilege?
HT thyrocytes	+	+	HT pathogenesis
Certain tumors	+	±	Immune escape

interest. Receptor trimerization appears to be critical to Fas-mediated signalling because pentameric immunoglobulin M (IgM) Fas-specific antibodies or Fas-specific antibodies that aggregate in solution (such as IgG3 isotype) act as potent Fas agonists. In contrast, dimeric Fas-specific antibodies (e.g. IgG1 isotype) do not signal through Fas unless they are cross-linked. In fact, dimeric Fas-specific antibodies can act as potent antagonists of FasL-induced apoptosis. The signalling cascade mediated by Fas has several features in common with that mediated by the p55 TNF-R. Both pathways utilize interleukin 1 β (IL-1 β)-converting enzyme (ICE)-like proteases, recently designated caspases ('c' for cysteine protease and 'aspase' referring to their ability to cleave after aspartic acid), as the effector components of the apoptotic pathway. The caspase genes are homologous to the ced-3 gene which is responsible for programmed cell death in the nematode *C. elegans*.

Although it has been clear for some time that caspases are responsible for the effector phase of apoptosis, the initial events that ultimately result in activation of these proteases have only recently begun to be elucidated. The currently available data indicate that binding of FasL to Fas induces trimerization of Fas and subsequent association of the cytoplasmic protein FADD/MORT1 (Figure 1). FADD is comprised of two domains, a C-terminal death domain (DD) that noncovalently associates with the DD of the cytoplasmic region of Fas, and a death effector domain (DED) at its N-terminus. Caspase-8 (FLICE/MACH/Mch5) then binds to FADD via their respective DEDs which results in the cleavage and release of the p20 and p10 subunits of caspase-8 and the formation of the active enzyme. Caspase-8 then mediates the production of active caspase-3 (CPP32/Yama/apopain) from its inactive pro-form and caspase-3, in turn, mediates proteolytic cleavage of poly-ADP ribose polymerase (PARP) and ultimately chromosomal DNA degradation. Caspase-6 (Mch2) and caspase-7 (Mch3) are also activated via the Fas apoptotic signalling pathway. Caspase-6 has been found to proteolytically degrade lamin A, whereas caspase-7 both cleaves PARP and contributes to the protease cascade via cleavage of procaspase-6. It seems unlikely that cleavage of a single substrate is sufficient to result in a lethal event to the cell. However, there appears to be a coordinated cascade of proteolytic events that are induced subsequent to the ligation of Fas, and it seems quite likely that it is the concerted cleavage of a variety of substrates that leads to the apoptotic death of the cell.

Why do some cells succumb to Fas-mediated death while others that express equivalent amounts of Fas resist apoptosis or instead become activated upon lig-

ation of Fas? The answer may lie in negative regulators of apoptosis. Bcl-2, which is a mammalian homolog of the *C. elegans* gene ced-9, is a member of a family of proteins that regulate apoptosis upstream of the caspases. Although it is well documented that Bcl-2 prevents apoptosis of cells triggered by a number of stimuli, including cytokine deprivation and chemotherapeutic drugs, its role in inhibiting Fas-mediated apoptosis is unclear. Interestingly, studies in which Bcl-2 transgenic mice were crossed with Fas deficient *lpr/lpr* mice have indicated that Bcl-2 regulation of apoptosis is largely independent of the Fas apoptotic pathway. Recent studies have indicated that Bcl-xL, which is another member of the Bcl-2/Ced-9 family, may be critical in inhibiting Fas-mediated apoptosis of B cells, whereas Fas-mediated apoptosis of T cells does not appear to be inhibited by either Bcl-xL or Bcl-2. CrmA, which is a cowpox virus protein that inhibits caspase activity, inhibits Fas-mediated death of T cells, though a mammalian homolog of this protein has not as yet been identified.

Immune function and regulation

Although Fas is expressed by many tissues and cell types, the expression of FasL is relatively restricted. Both CD8⁺ and CD4⁺ T cells, natural killer (NK) cells and lymphokine-activated killer (LAK) cells all express functional FasL and are capable of inducing apoptosis in Fas-expressing target cells. However, in spite of its expression by cytotoxic effector cells, in most instances FasL does not appear to play a critical role in CTL killing. Analysis of perforin gene deficient mice and mice mutated in the Fas pathway (*lpr/lpr* mice) has indicated that CTL killing of target cells is mediated primarily via the perforin/granzyme pathway. In accordance, mice that are perforin deficient are susceptible to many viral infections, whereas Fas-deficient mice mount a normal immune response to most pathogens.

T cells that recognize self antigens are eliminated primarily in the thymus by the process of negative selection. Interestingly, although Fas is expressed in the thymus and thymic subpopulations are susceptible to Fas-induced apoptosis, Fas does not appear to play a critical role in thymic T cell deletion. In particular, analysis of *lpr/lpr* and *gld/gld* mice has indicated that the Fas/FasL apoptotic pathway is not critical for T cell receptor (TCR) repertoire selection in the thymus. Instead, evidence has accumulated that Fas plays a pivotal role in the inactivation and removal of self reactive T cells in the periphery that have escaped thymic deletion. These peripheral self reactive cells are thought to die through the process

Figure 1 Fas apoptotic signaling pathway. Binding of trimeric FasL to its cognate receptor results in a coordinated cascade of cytoplasmic events leading to the activation of a series of cysteine proteases and ultimate death of the cell.

of activation-induced cell death (AICD) whereby previously activated T cells that are stimulated through the TCR undergo apoptosis. In this regard, the process of AICD in T cell clones and hybridomas is blocked by antagonists of Fas. Moreover, *lpr/lpr* and *gld/gld* mice are deficient in AICD as a result of mutations in Fas and FasL, respectively, thereby demonstrating a pivotal role for Fas/FasL interactions in this process. Finally, Fas/FasL interactions have been demonstrated to mediate peripheral but

not thymic deletion of antigen specific T cells in TCR transgenic mice.

Fas has also been implicated in regulating the duration of an immune response. Following a primary immune response, the vast majority of lymphocytes are eliminated by apoptosis (clonal downsizing) and only a small percentage survive to differentiate into effector and memory cells. Fas appears to play a critical role in clonal downsizing because mice that are defective in the Fas/FasL (*lpr/lpr* and *gld/gld*)

mice) pathway accumulate lymphocytes over time, resulting in splenomegaly and lymphadenopathy (Figure 2).

As mentioned earlier, expression of Fas does not always correlate with susceptibility to Fas-induced apoptosis. Most naive T cells either express Fas or can be induced to express Fas rapidly upon activation, though these cells do not die upon signaling via Fas. Instead, ligation of Fas on these T cells in the presence of T cell receptor cross-linking results in enhanced proliferation, increased expression of activation markers and increased cytokine production. Signaling via Fas in other cells, such as certain B cell lines and the HT-29 colon carcinoma cell line, can also result in activation and cytokine secretion rather than apoptosis. Upon continued stimulation, however, T cells become progressively susceptible to induction of apoptosis subsequent to cross-linking of Fas by either multimeric Fas-specific antibodies or FasL. Thus, the activation state of the cell appears to be a crucial determinant of whether

ligation of Fas results in T cell costimulation or apoptosis. In particular, cells in G_0 and G_1 are generally resistant to apoptosis, whereas they become sensitive to apoptotic stimuli as they enter the S phase of the cell cycle.

Apoptosis is also an important means of eliminating both self reactive and inappropriately activated B cells. B cells can be induced to express Fas and, depending upon the activation signals received, can become susceptible to Fas-induced apoptosis. For example, B cells activated by CD40 ligand (CD40L) in the absence of ligation of cell surface Ig become susceptible to Fas-mediated apoptosis. This may represent a mechanism for elimination of B cells that have been activated in a 'bystander' manner. In addition, B cells that have become desensitized by chronic stimulation with self antigens also become susceptible to Fas-mediated apoptosis and this may represent a means of eliminating 'anergic' B cells. In contrast, B cells that have been activated through their surface Ig receptor in conjunction with CD40L express Fas but are not susceptible to Fas-mediated apoptosis, and this appears to be mediated through the upregulation of Bcl-xL. Moreover, evidence from the study of antigen-specific B cells in Ig transgenic mice has indicated that Fas may play a role in conjunction with CD40L in the expansion of antigen-stimulated B cells, supporting the notion that ligation of Fas can transduce either apoptotic or activation signals and that the ultimate outcome depends upon other signals received by the responding cell.

Figure 2 Role of Fas and FasL in clonal downsizing of an immune response via activation-induced cell death (AICD). As target cells are eliminated, activated T cells expressing both Fas and FasL interact with one another, promoting clonal downsizing via AICD. Subsequently, FasL is downregulated following elimination of antigen and the remaining cells go on to form memory cells. (Reproduced with permission from Elsevier Science Ltd and Lynch *et al* (1995).)

Dysregulation of the Fas/FasL apoptotic pathway and pathological consequences

Natural mutations in the Fas and Fas ligand genes have provided insight into the role of these molecules in the immune system. As noted earlier, the autosomal recessive genes *lpr* (lymphoproliferation) and *gld* (generalized lymphoproliferative disease) are spontaneously derived mutations in mice that result in the development of progressive lymphadenopathy and splenomegaly. Mice homozygous for the *lpr* gene express very little Fas due to a mutation that interferes with expression of the full-length Fas protein. The phenotype of *gld/gld* mice results from a point mutation in the FasL gene that alters the ability of the translated protein to bind to its cognate receptor, Fas. Both mutant mouse strains have a phenotype characterized by hypergammaglobulinemia, auto-antibody production, glomerulonephritis, arthritis and vasculitis. Significantly, a functional human equivalent of the *lpr/lpr* mouse exists. Children with autoimmune lymphoproliferative syndrome (ALPS) have a phenotype that is very similar to the *lpr/lpr*

mouse, including a profound lymphadenopathy characterized by the expansion of CD3⁺CD4⁺CD8⁻ lymphocytes and hypergammaglobulinemia. This syndrome is the result of mutations in the Fas gene that result in premature truncations of Fas translation in a dominant interfering manner and a subsequent defect in Fas-mediated T cell apoptosis.

Just as deficiency in the Fas/FasL apoptotic pathway leads to lymphoproliferation (or more correctly lymphoaccumulation) and autoimmune disease, overexpression of this pathway can result in the unwanted elimination of cells. The finding that the loss of CD4⁺ T cells in individuals infected with HIV is due to inappropriate apoptosis has prompted many studies on the potential role of Fas in this process. Not only has Fas been shown to be upregulated in T cells from HIV patients but these T cells also show increased susceptibility to Fas-mediated apoptosis. Cross-linking of CD4 on T cells by immune complexes comprised of HIV gp120 and gp120-specific antibodies results in susceptibility to Fas-mediated cell death. Moreover, infection of macrophages with HIV or cross-linking of CD4 on macrophages induces expression of FasL and these cells can then induce apoptosis of activated T cells that have increased expression of Fas and become susceptible to Fas-mediated apoptosis. Thus, HIV-infected macrophages may be the prime mediators of apoptosis of bystander T cells in HIV⁺ patients progressing toward AIDS. Fas may also be involved in the progressive loss of CD4⁺ T cells in patients with idiopathic CD4⁺ T lymphocytopenia (ICL). T cells from these patients not only express elevated levels of Fas, but also constitutively express FasL (whereas T cells from normal donors do not) and have an increased rate of spontaneous T cell apoptosis *in vitro*.

A role for dysregulation of the Fas/FasL pathway has also been suggested in the progression of both hepatitis and Hashimoto's thyroiditis (HT). Although the role of Fas/FasL in these diseases differs mechanistically, together they illustrate how critical regulation of this apoptotic pathway is to prevent tissue pathology. Although FasL is constitutively expressed by thyrocytes, under normal conditions Fas is not. In HT, however, the data suggest that IL-1 upregulates expression of Fas and increases susceptibility to Fas-mediated apoptosis in thyrocytes. The coexpression of Fas and FasL in HT results in apoptotic loss of thyrocytes. On the other hand, hepatocytes constitutively express Fas and therefore infectious agents such as hepatitis B virus and *Propionibacterium acnes* that induce infiltration of FasL-expressing T cells into the liver can induce apoptosis of hepatocytes. Hepatitis in animal models

can be blocked by a soluble form of Fas and thus inhibitors of Fas may have potential in the treatment of diseases where Fas-mediated apoptosis results in disease progression.

Role of Fas/FasL in immune privilege and immune escape

Under normal conditions, transplantation of major histocompatibility complex (MHC)-mismatched tissues results in their rejection by a strong T cell response specific for alloantigens. There are, however, certain 'immune privileged' tissues, such as Sertoli cells in testis and corneal and retinal pigment epithelium in the eye, that are not rejected upon transplantation into an MHC-disparate host. Recent studies have demonstrated that these tissues avoid rejection because they constitutively express FasL. Thus, Sertoli cells from a normal mouse are not rejected upon transplantation into an MHC-mismatched host, whereas testis grafts from gld/gld mice (that have nonfunctional FasL) are immunologically rejected. It is thought that as the T cells that recognize the transplanted tissue become activated, they increase expression of Fas and become susceptible to Fas-mediated apoptosis and are killed by FasL expressed by the transplanted tissue. This raises the possibility that engineering tissues for transplantation to express FasL may help prevent allograft rejection. Indeed, cotransplantation of islets of Langerhans with myoblasts expressing FasL was found to prevent rejection of the graft and delayed onset of hypoglycemia in a mouse model for diabetes. Immune-privileged sites can also mediate induction of systemic T cell tolerance via Fas/FasL interactions. Thus, injection of antigen into the anterior chamber of the eye results in systemic tolerance to the antigen that requires that the eye be FasL⁺ and the lymphoid cells be Fas⁺.

A similar mechanism of elimination of activated T cells by constitutive expression of FasL may provide a means of escape from the immune system by tumor cells. Certain tumors, including a proportion of melanomas, colon cancer cells and hepatocellular carcinomas, have been demonstrated to constitutively express FasL and appear to use this as a means of evading the T cell immune response by eliminating tumor-reactive T cells as they become activated.

It has become clear in recent years that tight regulation of the Fas/FasL apoptotic pathway is critical not only in maintaining immune system homeostasis but also in modulating host responses to pathogens and tumor cells. Disruption of this pathway by cytokines, pathogens and carcinogens can clearly result in disease progression. Understanding of these

processes presents the opportunity for the development of novel therapies for certain diseases and manipulation of the immune response for induction of tolerance or immunity.

FASCIOLIASIS

Karen S Ovington, Division of Biochemistry and Microbiology, Faculty of Science, Australian National University, Canberra, Australia

Fascioliasis is a geographically widespread parasitic disease which is of economic importance because it lowers the productivity of livestock. Recently the disease has also been shown to be prevalent and clinically significant in humans in Latin America. The flat, leaf-shaped worms which cause this disease are digenetic trematodes of the genera *Fasciola* or *Fascioloides*. The common liver fluke, *Fasciola hepatica* (Figure 1), is considered here as it is the most prevalent and important species.

Characteristics of the organism and its antigens

Fasciola hepatica has an indirect life cycle. Many mammals, including sheep, cattle, rodents, marsupials and humans, can act as definitive hosts. Adult liver flukes, which are about 10 mm wide and 25 mm long, live in the bile duct, feeding on blood, bile and epithelial cells. The hermaphroditic adults reproduce sexually and release eggs which are carried in the bile

to the intestine. Eggs pass out with the feces and, if deposited in water, embryonate to form ciliated miracidia which hatch out and then swim until they find a snail of a suitable species. Asexual reproduction takes place in the snail to produce hundreds of cercariae. The cercariae burst out of the snail and, with the aid of a tail, swim until they reach vegetation, on which they rapidly encyst. The infective, metacercarial cysts have a sticky, multilayered protective casing. Mammals become infected by eating the lush but contaminated vegetation growing at the edge of the water.

Within the definitive host the metacercariae excyst in the small intestine to release juvenile flukes. The juvenile fluke moves through the intestinal wall, enters the peritoneal cavity and then penetrates the liver. Lobes of the liver closest to the duodenum are most heavily infected. The fluke grows rapidly as it migrates through the liver parenchyma, secreting proteolytic enzymes and feeding on liver tissue. Liver migration causes extensive damage with necrotic

Figure 1 Adult *Fasciola hepatica*.

tracks forming in the wake of the fluke. This is called the acute phase of infection and lasts from 3 to 7 weeks, depending on the species of host. The chronic phase begins when the juvenile fluke penetrates the wall of the bile duct and develops into a sexually mature adult. If the host is not reinfected, the liver parenchyma is repaired but the adult worms persist for many years, causing host morbidity and mortality.

A complex array of antigens are expressed during the migration and development of *F. hepatica*. Some are unique to specific developmental stages but others are common to all stages. Antigens are released from the alimentary canal and the tegument. Since liver flukes do not have an anus they must periodically regurgitate their gut contents so that they can continue feeding. Within the tegument there are electron dense secretory bodies, characteristic of the stage of the fluke, which secrete their contents on to the tegument. Tegumental antigens are released when the polyanionic outer layer, or glycocalyx, is shed. The host is also exposed to somatic antigens as typically only a small proportion of the metacerca-

riae establish as adult flukes in the bile duct. Somatic antigens will be released when flukes are damaged or dead.

Immune responses of the host

In the acute phase of a primary infection a pronounced inflammatory response occurs in the liver soon after infection. The tracks left by the fluke and the surrounding necrotic areas are infiltrated by neutrophils, eosinophils, lymphocytes (mainly CD4⁺ T cells in sheep), macrophages and hepatocytes. In all host species a prominent eosinophilia also occurs in the peritoneal cavity and the blood. There is, however, no cellular response around the juvenile flukes themselves. In the chronic phase of a primary infection many macrophages and fibroblasts are present in damaged areas. The liver becomes fibrotic. In sheep the fibrotic strands contain many CD8⁺ and $\gamma\delta$ -TCR⁺ T cells. The larger bile ducts become hyperplastic and infiltrated by many lymphocytes and eosinophils. In cattle a granulomatous reaction leads to calcification of the bile duct which may cause the loss of worms.

Primary infection in some host species, including cattle, rats and possibly humans, results in the development of resistance to reinfection, whereas in other species, including sheep and mice, this does not occur. The mechanisms of resistance appear to be different in cattle and rats. In secondary infections in cattle, incoming juvenile flukes are killed in the liver. Fibrosis of the liver is more severe in cattle than in other species and is thought to slow or prevent the migration of juvenile flukes, making them more vulnerable to immunological attack. In secondary infections in rats, juvenile flukes are killed before they reach the liver. Most are killed in the intestinal mucosa, even in nude rats. In transmission electron micrographs of intestinal tissues, tegumental damage to juvenile flukes was only noticeable near attached eosinophils. *In vitro* eosinophils, as well as the reactive oxygen intermediates and major basic protein they release, are toxic to juvenile flukes. Since an eosinophilia develops in T cell-deficient rodents infected with *F. hepatica*, the release of toxic products from eosinophils may kill juvenile flukes in the intestinal mucosa. In rats, any flukes which manage to pass through the intestinal mucosa are killed in the peritoneal cavity by T cell-dependent mechanisms which have not been fully elucidated but probably involve immunoglobulin IgG2a (IgG2a) and perhaps also eosinophils.

Sheep acquire large fluke burdens as they do not develop resistance to reinfection, and in subsequent infections inflammatory responses in the liver are

Figure 2 Life cycle of *Fasciola hepatica*.

similar to, but more pronounced, than those which occur in a primary infection. Sera from infected sheep recognize many of the *F. hepatica* antigens detected by sera from infected rats and can passively transfer resistance to naive rats. Overall, this suggests that deficiencies of cellular immune responses may account for the failure of sheep to develop resistance to reinfection (Figure 2).

Evasive strategies by the organism

Release of molecules from *F. hepatica* is thought to limit the effectiveness of the host's immune responses. Flukes secrete cathepsin proteases which cleave immunoglobulins and thus prevent attachment of host effector cells. Molecules which are toxic to host cells and thus immunosuppressive are also secreted. Juvenile flukes are also thought to be protected because they move from site to site, frequently shedding their glycocalyx as they do so.

Vaccines

Recent vaccine trials have produced promising and interesting results. Three purified *F. hepatica* antigens have potential as both immunodiagnostic and immunizing agents. The antigens are Fh12 (a 12 kDa *Fasciola/Schistosoma* cross-reactive antigen), glutathione S-transferase (GST) and cathepsin protease. The protective capacity of each of these has been tested in cattle or sheep. Cattle immunized with Fh12 had on average 55% fewer flukes than nonimmunized controls. Fh12 is a fatty acid-binding protein which is involved in intracellular transport of long-chain fatty acids and acyl CoA esters. Immunization with native *F. hepatica* GST had very variable effects, ranging from no effect at all to lowering fluke burdens by more than 90%. Cattle were more protected than sheep and the choice of adjuvant was found to be critical and to vary with host species. Reasons for the variability and the mechanism by which immune responses to *F. hepatica* GST lower fluke burdens are unclear. Vaccination of sheep with native cathepsin proteases had no effect on fluke burdens but fairly consistently lowered egg production by about 70%. The small number of eggs produced had low viability. These observations are consistent with cathepsin proteases being important in the formation

of the egg shell. Overall these vaccine trials have shown that sheep do not have an inherent inability to develop resistance to *F. hepatica* and have identified a number of antigens which induce protective immune responses by different mechanisms. This suggests that immunization of both cattle and sheep with a mixture of purified antigens could consistently and severely limit *F. hepatica* infections, which would be commercially useful.

FATTY ACIDS (DIETARY) AND THE IMMUNE SYSTEM

The nutritional status of the host can influence the immunological defense systems. Among the nutrients that affect the host, dietary lipids exert potent and pervasive effects on both the antigen-specific and nonspecific immune functions. Polyunsaturated fatty acids (PUFAs) have been employed successfully as preventive and therapeutic modalities to control the pathologic processes of several diseases in clinical trials and experimental animal models. Recent studies have addressed a large spectrum of issues related to the effects of dietary manipulations of n-3 PUFAs, principally linolenic acid (18:3) from plants and docosahexaenoate (22:6) from fish and algae, and n-6 PUFAs, principally linoleic acid (18:2) from plants and arachidonic acid (20:4) from animals and fungi. Studies in humans, rodents and other experimental animals have been reported on rheumatoid arthritis and other rheumatic diseases; coronary artery disease; immunosuppression after trauma; complications from infections; chronic fatigue syndrome; immune functions in the elderly; carcinogenesis; transplanted grafts and autoimmune diseases; alteration of tumorigenesis by modulation of macrophage function; antiviral activities against a thymic lymphoma-inducing retrovirus; changes in renal disease, inflammatory and immune-related disorders; and dermatological conditions.

The effects of dietary fatty acids on immune responses are related to 1) total and fat-derived energy intake, 2) production of myriad eicosanoids, and 3) changes in the composition of cell membranes. Some of the important dietary fatty acid effects on the immune system and their modes of action are summarized herein.

Total and fat-derived energy intake

Moderate calorie restriction prevents or delays the development of age-associated disease such as breast cancer and renal disease in rodents. Similar dietary manipulations may also alter the risk and rise of life-shortening diseases in humans. Consumption of a low calorie diet containing only 5% corn oil increases expression of interleukin-2 receptor, and enhances cell-mediated immune responses in rats. Age-associated diseases, particularly autoimmune diseases with viral etiology, appear to be intensified

by increased intakes of vegetable oils or *trans*-fatty acids from hydrogenated oils. In the USA, 35–40% of the total calories are from dietary fat. Although consumption of saturated fat, which has been associated with increased cardiovascular disease, has decreased during the past 50 years, consumption of both monounsaturated and PUFAs of n-6 origin has either increased or been substituted for saturated fats.

It has been suggested that intake of excess linoleic acid is a factor increasing the incidence of many chronic diseases, including cancer and thrombotic diseases. Many researchers have concluded that this reflects an imbalance of n-6 PUFAs versus n-3 PUFAs in diets. Excess intake of linoleic acid and changes in the essential fatty acid balance of diets may tend to predispose certain individuals to hyperreactivity to various allergens.

Increased n-6 PUFA intake, principally as vegetable oils, and decreased antioxidant intake may enhance the production of free radicals. Free radicals can decrease antioxidant enzyme mRNAs, and the resulting decreased levels of antioxidant enzymes can further affect immune function by decreasing production of anti-inflammatory cytokines such as interleukin 2 and tumor growth factor β mRNA levels. Cytokines are biologically-active peptides produced by immune cells. Since a high percentage of dietary PUFA can have a negative effect on the immune system, it is recommended that total fat intake be decreased so that 7–10% of dietary energy is consumed in the form of PUFAs and saturated fatty acids and 10–15% of monounsaturated fatty acids.

Eicosanoids

Eicosanoids are produced by the enzymatic oxygenation of n-6 and n-3 PUFAs. Eicosanoids are biologic mediators with myriad effects on immune cells. The n-3 PUFAs, especially eicosapentaenoic acid, competitively inhibit the utilization of the n-6 PUFA, arachidonic acid. Through the cyclo-oxygenase and lipoxygenase pathways, n-3 PUFAs are substrates for the production of biologically active products (thromboxane A₃ and leukotriene B₅ from eicosapentaenoic acid) that do not exert the same intensity of

action as those derived from n-6 PUFAs (for example, prostaglandin E₂ (PGE₂) and leukotriene B₄ from arachidonic acid). The overproduction of eicosanoids contributes to pathogenesis of chronic and acute inflammatory, autoimmune, atherosclerotic and neoplastic diseases. Feeding a fish oil (n-3 PUFA) diet restores splenic T cell blastogenesis, reduces splenic cell secretion of PGE₂ and alleviates splenic suppressor activity. In contrast, feeding a corn-oil diet (n-6 PUFA) to tumor-bearing mice suppresses cell-mediated immunity, with a concurrent increase in PGE₂ production.

Interactions between PUFAs and the immune system are influenced by the rate of their conversion to, and the efficacy of, the various eicosanoids. The rate of eicosanoid synthesis is determined by PUFA turnover, which depends on the activity of phospholipases and dietary alterations that affect the availability of n-6 and n-3 PUFAs in the phospholipid pool. Dietary n-3 PUFAs decrease the severity of certain autoimmune, inflammatory and atherosclerotic diseases by decreasing the production of n-6 PUFA-derived eicosanoids and cytokines.

The elevated levels of eicosanoids associated with shock and trauma can also induce immunosuppression in humans. The immunomodulatory mechanisms involved in providing such patients with an enteral diet containing n-3 PUFAs are controversial, however, most information available indicates that dietary supplementation with n-3 PUFAs may prevent immunosuppression after trauma. Rheumatoid arthritis patients taking dietary fish oil supplements exhibit improvements, such as a decreased number of tender joints. In short-term clinical studies, n-3 PUFAs seem to diminish cyclosporine-induced nephrotoxicity and the attendant complication of hypertension, to inhibit inflammatory and atherogenic mechanisms in lupus nephritis, and to preserve renal function and reduce proteinuria in immunoglobulin A nephropathy.

Feeding high levels of dietary PUFAs to mice and rats suppresses the lymphoproliferative response to polyclonal mitogens. Substitution of fish oil for olive oil as a vehicle for the administration of cyclosporine reduces cyclosporine-induced and eicosanoid-mediated acute nephrotoxicity in experimental animals. Concurrent administration of fish oil with a subtherapeutic dose of cyclosporine prolongs graft survival. Lymphocytes and macrophages derived from animals fed n-3 PUFAs as linolenic acid or fish oil markedly inhibits the mixed lymphocyte reaction, an indicator of graft survival. An allogeneic mixed lymphocyte reaction response in mice fed n-3 PUFAs as fish oil was less than the response of animals fed equal amounts of n-6 PUFAs.

Recent work suggests that alterations in the immune system caused by dietary fat may affect tumorigenesis. Studies have focused on dietary fat modulation of macrophage function because that cell plays a pivotal role in many immune responses, including antitumor activity. One possible mechanism by which dietary fat affects macrophages is altered signal transduction, which, in turn, could alter gene regulation and macrophage function. Arachidonic acid is a mediator of signal transduction through the protein kinase C pathway. In addition, arachidonic acid effects the transcription of a variety of genes. Interferon-associated arachidonic acid hydrolysis from membrane phospholipids induces transcription of the interferon-stimulated response element, and inhibition of the prostaglandin synthase and 5-lipoxygenase pathways enhances this signal.

Membranes

Changes in the physical properties of membranes with aging or dietary lipids may influence the sensitivity of immune cells to antigenic stimuli. Dietary fatty acids can modulate the biosynthesis of eicosanoids from arachidonic acid by increasing the ratio of n-3:n-6 PUFAs in the membrane phospholipids and by modulating the biosynthesis of eicosanoids via the cyclo-oxygenase and lipoxygenase metabolic pathways. The rate of uptake and conversion of linoleic acid to arachidonic acid is age dependent and is genetically controlled. The availability of the direct precursor fatty acid is a limiting factor in eicosanoid biosynthesis. Biological responses similar to those seen with eicosanoids can be modified by manipulation of the composition of dietary lipids that influence the fatty acid composition of various tissues, including immune competent cells (e.g. macrophages, platelets, T cells, B cells, etc.). The n-3:n-6 PUFA ratio of various tissue phospholipids correlates with the n-3:n-6 PUFA ratio of the diet. An increased incorporation of n-3 PUFAs increases the n-3:n-6 fatty acid ratio in platelets and macrophages. Linoleic acid is the sole fatty acid required to support proliferation and maturation of immunoglobulin-secreting cells. Suppression of B cell functions may be caused by displacement of linoleic acid and arachidonic acid by n-3 PUFAs. Enhanced B cell functions in animals fed unsaturated fatty acids and corn oil could be due to an increase in the incorporation of linoleic acid and arachidonic acid in the membrane phospholipids.

The lipid composition of cell membranes plays a pivotal role in the mediation of the primary and secondary immune responses against an antigenic challenge or to an infection. Ongoing studies that are

showing how dietary fatty acids can profoundly affect immune functions may provide a basis for future therapeutic intervention.

Fc RECEPTORS

Neil A Fanger, Department of Physiology, Dartmouth Medical School, Hanover, New Hampshire, USA

Michael W Fanger, Departments of Microbiology and Medicine, Dartmouth Medical School, Hanover, New Hampshire, USA

Paul M Guyre, Department of Physiology, Dartmouth Medical School, Hanover, New Hampshire, USA

Fc receptors (FcRs) are molecules expressed on the surface of a variety of cells that recognize and bind the Fc region of certain immunoglobulin (Ig) classes and subclasses. Hematopoietic cell FcRs specific for IgG (FcγR), IgA (FcαR) or IgE (FcεR) have been well characterized and their genes have been cloned (Figure 1). Some data suggest the existence of FcRs for IgM and IgD on leukocytes, although structural entities for such receptors have not been well defined. In addition, two epithelial cell FcRs have been well characterized: FcRn which mediates both IgG transport across the placenta and IgG uptake by neonatal intestinal epithelium, and the pIgR (poly Ig receptor, also known as secretory component) which transports IgA into mucosal secretions.

The high- and medium-affinity hematopoietic cell receptors for IgG (FcγRIa and FcγRIIIa, respectively) and the high-affinity receptor for IgE (FcεRI) bind monomeric Ig cytophilically, 'arming' the effector cell for subsequent interaction with antigen. All other FcRs appear to react only with Ig-coated (opsonized) cells or with antigen–antibody (Ag–Ab) complexes. Recognition is of the native Fc structure, not of new Fc region epitopes that might result from formation of Ag–Ab complexes. Rather, the increased avidity of Ag–Ab complexes for FcR interaction results from the multivalent interactions of numerous cell-associated Fc receptors with an array of Ig Fc regions associated with the antigen.

The initiation of most biological events upon ligand binding to FcR requires receptor cross-linking. Even for high-affinity receptors, binding of monomeric Ig is insufficient to transmit an activation signal, although recycling of high-affinity receptors to which monomeric ligand has bound probably does occur. The nature of the biological response initiated by cross-linking FcRs depends on the class and subclass of FcR and the cell type on which the FcR is displayed. This response ranges from very rapid degranulation upon cross-linking of FcεRI on mast cells, to inflammatory mediator release and/or killing of the Ig-coated pathogens by antibody-dependent cellular cytotoxicity (ADCC) or phagocytosis following engagement of FcγR, FcαR, or FcεR on many types of effector cells, to regulation of B cell activation by both cell surface and soluble forms of FcR.

Comparable receptors exist in many animal systems, but are generally less well characterized than the human FcR. The following discussion therefore focuses on the biochemical and biological properties of human FcR.

Fc receptors for IgG (FcγR)

The FcγRs, by triggering phagocytosis, ADCC, and release of mediators, represent the primary effector molecules involved in the removal of IgG-coated pathogens by monocytes, macrophages, neutrophils

Figure 1 Fc receptor structures. Each of the Fcγ receptors, the FcαR and the α chain of FcεRI are members of the immunoglobulin gene superfamily. FcεRII is a member of the C-type animal lectin family.

and eosinophils. On large granular lymphocytes (LGL)/natural killer (NK) cells, these receptors mediate efficient non-major histocompatibility complex(MHC)-restricted cytotoxicity of virus infected and tumor cells. Platelets respond to FcγR cross-linking by mediator release and expression of adhesion-related activation antigens, resulting in platelet aggregation. B cell FcγRs are involved in the regulation of cell activation and immunoglobulin production. In addition to these beneficial effects, the FcγRs are also involved in autoimmune diseases. IgG autoantibody-coated red cells, platelets, etc., are removed through interactions with FcγRs on tissue macrophages.

Distribution and properties of FcγR (Table 1)

FcγRIa, the only isoform of CD64 that has been characterized at the protein level, is a 72 kDa glycoprotein which is recognized by monoclonal antibodies (mAbs) 32, 22, 197 and 10.1. Although FcγRIb2 mRNA is coexpressed with the FcγRIa message, corresponding proteins have not been identified for this or the FcγRIb1 and FcγRIc transcripts. FcγRI is the receptor with the highest affinity for monomeric IgG, having an equilibrium dissociation constant (K_d) of 10^{-8} to 10^{-9} M for human IgG1 and IgG3, and mouse IgG2a and IgG3. FcγRI is therefore occupied by IgG under physiologic conditions. It is expressed constitutively by only monocytes, macrophages and dendritic cells, but cytokines can induce its expression on granulocytes. FcγRIa requires associated γ chains for stable expression and activation of phagocytic signaling, but can appar-

ently mediate Ig uptake in the absence of associated molecules.

FcγRII (CD32) is a family of related 40 kDa glycoproteins identified by several mAbs, including IV.3, KB-61 and AT-10. Different FcγRII isoforms are found on different hematopoietic cells, as well as on endothelium. All forms of FcγRII have low affinity for monovalent human IgG, and appear to bind only immune complexes and opsonized particles. The cytoplasmic domains of members of the CD32 family contain typical ITAMs (immunoreceptor tyrosine-based activation motifs) or ITIMs (immunoreceptor tyrosine-based inhibitor motifs) which enhance or inhibit effector functions, respectively.

FcγRIII (CD16) was originally identified as a 50–70 kDa glycoprotein which is recognized by various mAbs including 3G8, Gran1 and B73.1. Two isoforms of FcγRIII exist. On neutrophils, the isoform designated FcγRIIIb has low affinity for IgG, lacks a cytoplasmic domain, and is bound to the membrane through a phosphatidylinositol glycan (PIG) linkage. On macrophages and LGL/NK cells, the isoform designated FcγRIIIa is a transmembrane molecule containing a typical cytoplasmic domain. The latter has an intermediate affinity for IgG ($K_d \sim 3 \times 10^{-7}$ M) and is expressed in association with signaling molecules including ζ and γ chains.

Genes encoding the FcγR

Eight different genes coding for human FcγR have been defined, and are transcribed into at least 12 different mRNAs. Along with the FcεRIα gene, all are localized to the long arm of chromosome 1, band

Table 1 Properties of the Fc receptors

Receptor	Mol. wt (kDa)	Affinity	CD	Distribution	Associated molecules
FcγRI	72	High	64	Monocytes, macrophages, dendritic cells, neutrophils ^a	γ chain
FcγRIIa	40	Low	32	Monocytes, macrophages, granulocytes, platelets, endothelial cells	γ chain
FcγRIIb	40	Low	32	B Cells, monocytes, macrophages	None described
FcγRIIc	40	Low	32	Monocytes, macrophages, granulocytes, platelets	None described
FcγRIIIa	50–70 ^b	Medium	16	Macrophages, LGL/NK	γ chain ζ chain
FcγRIIIb	50–70 ^b	Low	16	Neutrophils	None described
FcαR	55–100 ^b	Medium	89	Monocytes, macrophages, neutrophils, eosinophils	γ chain
FcεRI	α,45; β,33; γ,8	High	ND	Mast cells, basophils, dendritic cells, eosinophils	β chain γ chain
FcεRII	45	Low	23	B Cells, T cells, eosinophils, platelets, monocytes, macrophages	None described

^aNeutrophil CD64 is very low; increased by IFNγ and G-CSF.

^bMolecular weight varies due to differential glycosylation.

q23–24. Expressed proteins have been identified for six different Fc γ R isoforms (Fc γ RIa, IIa, IIb1, IIb2, IIIa and IIIb); it is unknown in which cells, if any, the remaining predicted mRNAs are expressed. Sequence homology indicates that all are members of the Ig gene superfamily. The Fc γ RII and III molecules have two extracellular Ig-like domains, while Fc γ RI has a third extracellular domain which imparts its higher affinity for IgG. Allelic variants of the Fc γ RIIIa and Fc γ RIIIb genes have been described which result in polymorphisms in expression and function of these receptors, and have been associated with altered susceptibility to infectious and immune complex diseases.

Modulation of Fc γ R expression

Although strict measurement of the number of receptors per cell has not been made for many cell types, estimates based on quantitative flow cytometry have been obtained. Fc γ RI is almost exclusively restricted to monocytes (15 000–40 000 per cell), macrophages (>50 000 per cell) and dendritic cells (3000–20 000 per cell). Less than 1000 Fc γ RI sites are found on freshly isolated granulocytes of healthy subjects, while there are 5000–20 000 receptors per cell when neutrophils are cultured with interferon γ (IFN γ) or are obtained from people who have bacterial infections. IFN γ also causes a 5- to 10-fold increase in the number of Fc γ RI on monocytes, monocyte-derived macrophages, alveolar macrophages, peritoneal macrophages, dendritic cells and human myeloid cell lines. Granulocyte colony-stimulating factor (G-CSF) and interleukin 10 (IL-10) also induce increased Fc γ RI expression, but to a lesser extent than IFN γ . Certain other cytokines, such as IL-4 and IL-13, decrease Fc γ RI expression.

Different Fc γ RII isoforms are expressed on the surface of virtually all hematopoietic cells except erythrocytes. Fc γ RIIIa is found in similar numbers (20 000–40 000 sites per cell) on monocytes, macrophages and neutrophils. Its expression on myeloid cells is increased by granulocyte-macrophage colony-stimulating factor (GM-CSF) and inhibited by IL-4 and IL-13. Fc γ RIIIa is probably the sole Fc γ R on human platelets, whereas Fc γ RIIIb isoforms predominate on B lymphocytes.

Fc γ RIIIb is expressed at high levels (100 000–200 000 sites per cell) only on human neutrophils, and is shed or internalized in response to neutrophil activation or exposure to tumor necrosis factor α (TNF α). The Fc γ RIIIa isoform is expressed by only a small subset of human monocytes, whereas macrophages and LGL/NK cells express high levels of this receptor. Culture of monocytes, particularly in the presence of exogenous transforming growth factor β

(TGF β), increases expression of Fc γ RIIIa. Although its expression does not appear to be modulated by IL-2 and IFN γ , these cytokines enhance macrophage cytotoxic activity triggered via Fc γ RIIIa.

The Fc receptor γ chain is essential for phagocytosis and ADCC triggered through Fc γ RI, and can also participate in signal transduction following engagement of Fc γ RII and Fc γ RIIIa. IFN γ induces higher expression of γ chain, and this may account for some of the enhanced functions of leukocytes following activation by IFN γ .

Functional properties of Fc γ R

Mononuclear phagocytes Fc γ RI, Fc γ RII and Fc γ RIII all act as trigger molecules for phagocytosis and ADCC, the latter requiring engagement of adhesion molecules (e.g. LFA-1) for maximal efficiency. IFN γ enhances monocyte-mediated killing through Fc γ RI, especially when limited antibody is available on the target. In contrast, IFN γ does not enhance monocyte expression of Fc γ RII or Fc γ RIII. Although little Fc γ RIII is expressed on freshly isolated monocytes, this receptor is induced when monocytes mature into macrophages. Monocytes cultured for even short periods mediate lysis of tumor cells through Fc γ RIII. In addition, antigen-specific T cell activation is markedly enhanced when the antigen is targeted to either Fc γ RI or Fc γ RII on monocytes or dendritic cells.

Neutrophils Freshly isolated neutrophils do not lyse nucleated targets through Fc γ R. However, when cultured with IFN γ , they mediate killing through Fc γ RI and Fc γ RII. Killing through Fc γ RI correlates with the induction of this receptor on the neutrophil by IFN γ , whereas, IFN γ renders neutrophils capable of cytotoxicity via Fc γ RII by inducing changes which potentiate cytotoxic mechanisms, without increasing Fc γ RII expression. Neutrophil-mediated cytolysis of red blood cells occurs through Fc γ RII and Fc γ RIII, and incubation with IFN γ enhances cytotoxicity through Fc γ RII but not Fc γ RIII. GM-CSF also significantly enhances killing by neutrophils through Fc γ RII, again without affecting expression of Fc γ RII. Fc γ RIII on neutrophils does not mediate cytotoxicity of tumor targets. These observations suggest that erythroid and tumor targets are killed through different pathways, and that triggering of Fc γ RI or Fc γ RII on neutrophils activates lytic mechanisms distinct from those initiated via Fc γ RIII.

Eosinophils Although freshly isolated eosinophils do not kill tumor targets, after activation with GM-CSF they mediate killing through Fc γ RII but not Fc γ RIII, even though both Fc γ Rs are expressed on

these cells. Thus, like neutrophils, eosinophils require lymphokine activation to perform ADCC of tumors through Fc γ RII. Fc γ Rs have also been shown to mediate ADCC of parasites by eosinophils after activation by GM-CSF, TNF or IL-5.

Large granular lymphocytes and NK cells LGL/NK cells very efficiently mediate ADCC of tumor cells through Fc γ RIIIa. This contrasts with the inability of Fc γ RIIIb on neutrophils to mediate tumor cell killing, but is consistent with the cytolytic ability of macrophage Fc γ RIIIa. This difference correlates with the presence of transmembrane and cytoplasmic domains and/or association with γ or ζ chains, which occurs for Fc γ RIIIa only, and appears to be required for signaling pathways resulting in lysis of tumor cells.

U937, HL-60 and THP-1 cells Myeloid cells representing various steps in monocyte differentiation have facilitated evaluation of the functional maturation of the different Fc γ Rs. Although these cell lines express Fc γ RI and Fc γ RII, and are induced to express much larger numbers of Fc γ RI by IFN γ , they do not lyse tumor targets through Fc γ Rs, even after treatment with cytokines. They are, however, able to mediate ADCC of red cells through Fc γ RI and Fc γ RII after IFN γ or G-CSF treatment.

Fc γ Rs in infectious disease

In addition to their role as cytotoxic trigger molecules which mediate killing of opsonized tumors and pathogens, Fc γ R have been shown, under certain conditions, to mediate enhanced infection by certain infectious agents. For example, Fc γ Rs play a major role in dengue virus infection of human mononuclear phagocytes and the pathogenesis of the disease caused by this virus, as the rate of infection is markedly enhanced when these cells encounter antibody-coated virus. Human immunodeficiency virus type 1 (HIV-1) infection of monocytes and macrophages is also enhanced by opsonization of the virus with very small amounts of antibody. It would appear however, based on studies using bispecific antibodies, that Fc γ Rs are not infectivity receptors for HIV, but rather increase cell contact with the virus, enhancing its ability to interact with CD4 on the cell and in this way contribute to enhanced infectivity. Such findings must obviously be taken into account in strategies for the development of vaccines for these and other intracellular pathogens.

Fc receptors for IgE (Fc ϵ R)

IgE-binding proteins subserve a variety of functions. The type I Fc ϵ R, a multimeric complex once thought to be exclusively expressed by mast cells and basophils, has more recently been identified on eosinophils, monocytes, Langerhans cells and blood dendritic cells. Thus, in addition to playing a central role in the release of inflammatory mediators in atopic disease, it may also facilitate antigen uptake by antigen-presenting cells. The low-affinity type II Fc ϵ R (CD23), which bears no homology to Fc ϵ RI, is found on B cells, eosinophils, monocytes, Langerhans cells, platelets and probably T cells. Fc ϵ RII is a B cell differentiation antigen and also a trigger molecule for IgE-mediated lysis of parasites by myeloid cells. Soluble Fc ϵ RII is found in the blood, and appears to influence B cell differentiation and monocyte migration.

Distribution and properties of Fc ϵ R

Fc ϵ RI is highly expressed (>100 000 sites per cell) on mast cells and basophils, where it consists of a heterotetrameric complex containing one α , one β and two γ polypeptide chains (Figure 1). It appears at lower levels on a variety of other cells (Table 1), where its association with accessory molecules may be different. It binds the C ϵ 2 and C ϵ 3 domains of the Fc region of IgE with high affinity ($K_d = 10^{-10}$ M) via the glycosylated α chain of the receptor. The γ chains are essential for efficient and stable expression of the receptor on the cell surface, and are also required for signal transduction.

Fc ϵ RII is a single-chain glycoprotein (Figure 1) which exists in two forms (Fc ϵ RIIa and Fc ϵ RIIb) that differ only in their cytoplasmic tails. Fc ϵ RIIa appears to be restricted to B lymphocytes, while Fc ϵ RIIb has been found on B cells, T cells, eosinophils, platelets, monocytes, macrophages, Langerhans cells and human myeloid cell lines such as U-937. The C ϵ 3 domain of IgE is involved in binding to this receptor. A soluble form of Fc ϵ RII, termed IgE-binding factor (IgE-BF) or soluble Fc ϵ RII/CD23 (sCD23), appears to be released from CD23⁺ cells by an autocatalytic mechanism, although alternative transcripts encoding for a soluble CD23 have been defined.

Genes encoding Fc ϵ R

The cDNA for the α subunit of Fc ϵ RI encodes a polypeptide with structural similarity to the Fc γ receptors. There are two immunoglobulin-related extracellular domains, a transmembrane domain containing eight residues that are identical to those of Fc γ RIIIa, and a relatively unique cytoplasmic domain consisting of 31 amino acids. The cDNA for

the β subunit predicts four transmembrane domains and no homology to the immunoglobulin gene superfamily. The cDNA for the γ subunit indicates homology with the ζ chain which is expressed both in association with Fc γ RIIIa on large granular lymphocytes and with the T cell receptor (TCR) complex on T cells. The γ chain consists of five extracellular amino acids, a single transmembrane domain and a 42 residue cytoplasmic tail.

The two forms of Fc ϵ RII (Fc ϵ RIIa and I Ib) arise from alternative splicing of a single gene. Both molecules consist of 321 amino acids with the C-terminus on the outside of the plasma membrane, no leader sequence, and a single transmembrane domain. The I Ia and I Ib forms differ only at seven residues in the N-terminus, and share apparently identical extracellular C-terminal domains.

Modulation of Fc ϵ R

Fc ϵ RI is uniformly distributed throughout the plasma membrane, but is rapidly aggregated and internalized upon cross-linking of receptor-bound IgE. The expression of Fc ϵ RII is increased by elevated IgE levels, apparently by protection from degradation to the soluble form. IL-4 and IFN γ upregulate CD23 expression by increasing Fc ϵ RII synthesis, while IFN α suppresses Fc ϵ RII expression.

Functional properties of Fc ϵ R

Fc ϵ RI is expressed on antigen-presenting cells, such as monocytes and Langerhans cells, are able to enhance antigen presentation to T cells. The cross-linking of Fc ϵ RI on mast cells and basophils, in contrast, triggers phosphoinositide hydrolysis, mobilization of cytoplasmic calcium, influx of extracellular calcium, explosive release of granular components such as histamine, and synthesis of potent inflammatory mediators, such as leukotrienes and platelet-activating factor. A large number of cytokines are also released in response to Fc ϵ RI triggering, including IL-1, IL-3, IL-4, IL-5, IL-6, TNF α , IFN γ , GM-CSF, macrophage inflammatory protein 1 α (MIP1 α) and MIP1 β . These may contribute markedly to the inflammatory reaction associated with mast cell degranulation.

Fc ϵ RII on macrophages, eosinophils and platelets can mediate cytotoxicity and/or phagocytosis of IgE-coated particles. In addition, aggregated IgE triggers release of reactive oxygen metabolites and other inflammatory mediators from Fc ϵ RII-bearing cells. Thus, on some cell populations this receptor may be involved in inflammation and/or removal of IgE-coated agents. On other cells (e.g. B cells, Langerhans cells), Fc ϵ RII may be involved in modulation of the isotype of humoral immune responses and

enhancement of antigen presentation. Moreover, soluble Fc ϵ RII appears to play a role in B cell growth and differentiation, and in association with IL-4, enhances IgE synthesis.

Fc receptors for IgA (Fc α R)

IgA fulfills a critical protective role against the constant environmental insults encountered at mucosal surfaces. Although the mechanism of protection is not well understood, the IgA-mediated mucosal immune response may be at least partially manifest through binding of IgA-coated targets to Fc receptors for IgA on effector cells. Monocytes, macrophages, neutrophils, eosinophils and myeloid cell lines express cell surface IgA Fc receptors (Fc α R; CD89) consisting of a 50–70 kDa molecule which, like Fc γ RI, Fc γ RIIIa and Fc ϵ RI, associates with the signal-transducing γ chain. The IgA-binding chain contains a 206 amino acid extracellular domain including six potential sites for N-linked glycosylation, a feature that, along with O-glycosylation, accounts for the significantly higher molecular weight observed for native Fc α R. The extracellular region is followed by a 19 residue transmembrane region and an intracytoplasmic region of 41 amino acids. Sequence analysis indicates that Fc α R is a member of the immunoglobulin superfamily and is homologous to other known Fc receptors (Figure 1). Binding of monomeric IgA probably occurs under physiological conditions, but binding *per se* does not trigger function. Rather, cell signaling for phagocytosis, ADCC, degranulation, and/or inflammatory mediator release requires receptor cross-linking.

Various cytokines play a role in regulating Fc α R expression and function by monocytes, macrophages and neutrophils. LPS, in addition to TNF α and IL-1, which are produced in response to LPS, strongly upregulate monocyte Fc α R expression, as does GM-CSF. Increases in Fc α R-specific mRNA are also detectable following monocyte stimulation with either TNF α , IL-1, GM-CSF or LPS. IFN γ , in contrast, downmodulates both surface expression of Fc α R and intracellular Fc α R-specific mRNA levels. These results indicate that Fc α R on monocytes are modulated by endotoxin and an array of cytokines distinct from those that regulate expression of FcRs for IgG.

Summary

The distinct human FcR classes perform discrete tasks, with their function largely dictated by the receptor isoform and the cell type on which they are displayed. Receptor signaling is mediated both

through phosphorylation domains in the cytoplasmic tail of the ligand-binding α chain (e.g. Fc γ RII), and via associated molecules such as γ - or ζ -chains (e.g. Fc γ RI, Fc γ RII, Fc γ RIIIa, Fc ϵ RI and Fc α R). FcRs have in common the requirement for receptor cross-linking to trigger most cell functions, with the probable exception of endocytosis. Cytokines modulate both FcR expression and function, but sometimes in opposite directions. In some cases, FcR function is enhanced without any overt change in receptor expression (e.g. in response to G-CSF or GM-CSF). It seems likely that the specific tissue microenvironment which dictates the overall molecular interactions of the FcR-bearing cell plays a crucial role in the ultimate level of function that is triggered by engagement of FcR.

FELINE IMMUNE SYSTEM

Ian R Tizard, Department of Veterinary Pathobiology, The Texas Veterinary Medical Center, Texas A&M University, Texas, USA

The immune system of the cat possesses no unique structural elements and it is safe to assume that in its basic features it conforms to the pattern seen in other placental mammals. Nevertheless, the feline immune system does show some interesting and unique differences, described here.

Lymphoid tissues

Cats, like ruminants and pigs, possess a population of pulmonary intravascular macrophages. These cells are considerably more important than the Kupffer cells in removing particulates from the bloodstream. Thus 86% of injected streptococci were removed in the lungs as opposed to 14% in the livers of cats. The presence of this population of cells may explain

why cats are more susceptible than other mammals to septic shock mediated by macrophage-derived tumor necrosis factor (TNF). The lymph nodes, spleen, tonsils, Peyer's patches, bone marrow and thymus are of comparable structure to that seen in other mammals. The thymus appears in fetal kittens at 28 days after conception.

Feline lymphocytes

About 40–45% of feline peripheral blood lymphocytes are identifiable as B cells. The ontogeny of B cell development is similar to that seen in other animals. Pre-B cells have been identified at 42 days after conception in the fetal kitten liver. Subsequently, they

are found in the spleen and bone marrow. Adult levels of B cells are reached in the kitten by 12 weeks of age.

About 32–41% of peripheral lymphocytes are identifiable as T cells. Feline T cells also form E rosettes with red blood cells from guinea pig, mouse and rat. Guinea pig erythrocyte receptors appear to be the most satisfactory T cell markers and are found on both differentiated and undifferentiated T cells. Both T helper and T suppressor cell activities have been identified in the cat. About 20% of feline peripheral blood lymphocytes lack both T and B cell markers. These null cells, found both in immune and nonimmune animals, can destroy tumor cells or virus-infected cells. They are thus assumed to be natural killer (NK) cells. NK cell activity against herpes simplex-infected target cells has been demonstrated in cats.

The mitogenic responses to phytohemagglutinin (PHA), concanavalin A (Con A) and pokeweed mitogen (PWM) are primarily a property of T cells, although feline lymphocytes respond relatively poorly to PHA and lipopolysaccharide in comparison to other mammals. Feline analogs of CD4 and CD8 have been identified and several monoclonal antibodies to undefined lymphocyte cell membrane antigens have been described. fCD molecules that have been identified include CD5, CD9, CD10, CD18 (LFA- β chain) and CD45R. Such evidence as is available suggests that these molecules are very similar to their equivalents in mice and humans.

Feline cytokines

The molecular weight of feline interleukin 1 (IL-1) ranges from 15 to 20 kDa. As in other species, it occurs in three different isoforms. IL-1 is released in large quantities from peritoneal macrophages in cats infected with the coronavirus of feline infectious peritonitis and may play a part in the development of the lesions in that disease. It is also released by lipopolysaccharide-treated alveolar macrophages.

Feline IL-2, released by the action of Con A on lymphocytes, has a molecular weight of 16 kDa. It supports the proliferation of Con-A-activated feline peripheral blood lymphocytes. IL-2 production is significantly decreased in cells from cats infected with feline leukemia virus (FeLV). IL-2-containing cell supernatants can stimulate the development of cytotoxic activity (LAK) in peripheral blood lymphocytes from normal cats. The target in this case was the feline lymphoblast cell line FL74, which continuously produces FeLV.

Feline IL-6, derived from Con-A-stimulated splenocytes, has a molecular weight of 30–40 kDa. Its physicochemical properties are somewhat different from the human and mouse analogs.

Interferons α , β and γ have been characterized and resemble those in other species. Interferon produced *in vitro* by Newcastle disease virus-stimulated Crandall feline kidney cells will make the cells resistant to invasion by FeLV and vesicular stomatitis virus (VSV).

Feline immunoglobulins

Cats probably possess all the immunoglobulin (Ig) isotypes seen in other species, although neither IgE nor IgD have been formally identified. Adult cat sera, colostrum whey, tears and nasal secretions contain IgG, IgM and IgA. Electrophoretic analysis suggests that there are at least three IgG isotypes – G1, G2 and G3 – and preliminary evidence suggests the existence of a fourth. A reagenic antibody obtained from a cat infected with the microfilariae of *Brugia pahangi* has been characterized and had properties compatible with IgE. Given the recent evidence that some mammals, pigs for example, have no δ chain genes and cannot make any IgD, it is not unlikely that cats may also lack this isotype. Lambda (λ) is the predominant light chain type in the cat, accounting for 80–90% of light chains. In common with other mammals with placentas impermeable to immunoglobulins, female cats are obliged to transfer antibodies to their offspring through colostrum. As a result, IgG, IgM and IgA are present in colostrum whey in high concentrations (Table 1). As lactation proceeds and immunoglobulin levels drop, IgG remains the major immunoglobulin class in cat milk. IgM and IgA are the predominant immunoglobulins in cat bile. IgA is the predominant immunoglobulin in intestinal and respiratory mucus and in tears. As in other species, cat secretory IgA is a J chain-linked dimer. Immunoglobulins cannot be detected in the urine of adult cats but may be found in the urine of suckling kittens. This may reflect the excretion of small immunoglobulin fragments absorbed by the intestine from colostrum.

While IgE has been functionally identified in the cat by methods such as passive cutaneous anaphylaxis, it has not been physicochemically characterized. Feline IgE is weakly reactive with human and bovine anti-IgE, as measured by the ability of feline atopic serum to block an ELISA test for bovine IgE.

Table 1 Serum immunoglobulins in the cat (mg ml⁻¹)

Source	IgG	IgM	IgA
Serum	7.2–19.7	0.8–1.9	0.7–2.8
Colostrum	44.0	0.6	3.4
Milk	1.5	0	0.2

Cell-mediated immunity

Cats infected with tuberculosis respond poorly to intradermally injected tuberculin and, as a result, the tuberculin test is unsatisfactory in this species. They do not respond with delayed hypersensitivity reactions to proteins such as bovine serum albumin. Nevertheless, cats can develop a good delayed skin response to dinitrochlorobenzene, to viral antigens and to BCG vaccine, although these delayed hypersensitivity reactions are not as intense or as consistent as in other species, such as the guinea pig. Despite this lack of skin reactivity, the granulomatous reactions to tuberculosis in the cat are indistinguishable from those seen in other mammals.

Feline major histocompatibility complex (MHC) molecules

The feline histocompatibility (FLA) system has been unusually difficult to study because the conventional approach of generating lymphocytotoxic antibodies by transfusion, multiple births or skin grafting does not work well. (Only about 25% of cats rejecting allografts produce lymphocytotoxic antibodies.) It may also be difficult to produce substantial mixed lymphocyte culture reactivity between some unrelated feline cells. Although it is possible that this may be due to a lack of FLA polymorphism, it is more likely to be due to a relatively low level of MHC expression on cat mononuclear cells. Thus genetic analysis indicates that the FLA system contains 10–20 class I gene loci, of which only two are expressed. Cats also possess five class II gene loci, of which only three are expressed. Feline class I antigens display 81–82% sequence identity with the human and 73–79% identity with the mouse homologs. Analysis of the histocompatibility antigens of other felids suggests that their MHC has a similar structure. Cat class I and class II MHC genes are located on chromosome B2.

The lack of MHC polymorphism in the cat may help to account for the ease of bone marrow transplantation in this species. The success rate of bone marrow allografts in cats previously treated with X-radiation or cyclosporine is high and graft-versus-host disease is not a major problem.

Feline complement

Cats possess all the major complement components at levels comparable to those in other species of mammal. Cat complement is, however, not as hemolytic as rabbit, dog or guinea pig complement when using rabbit antibodies and sheep erythrocytes as antigens.

Feline hypersensitivity

The lungs are the primary target organ for anaphylactic shock in the cat, and serotonin release from mast cells is probably the most important mediator of anaphylaxis. Flea-bite dermatitis is the most common allergic reaction in cat skin, whereas allergic rhinitis is rarely encountered. Food hypersensitivity has been described in the cat.

Feline blood groups and hemolytic disease

There are only two feline blood group antigens, called A and B. The prevalence of each of these two antigens varies according to geographical region. Thus, in the USA, 99% of cats are group A and only 1% are group B. In contrast, in Australia, 73% of cats have group A erythrocytes, while the rest are group B. Blood group B tends to be found in more exotic breeds of cats rather than in the common domestic shorthair. Very rare AB (0.4%) cats have been described. About 20% of group A cats possess natural anti-B with titers ranging from 16 to 512. Group B cats invariably contain anti-A at high titer. Agglutination and hemolysis can be used for feline blood typing.

Neonatal isoerythrolysis has been recognized in the cat. It may be induced artificially by immunization of queens with vaccines containing feline blood components. It has also been reported to occur spontaneously when sires of blood group A are bred repeatedly to females of blood type B. The antibodies are transferred from the mothers to the kittens through their colostrum. These then cause massive erythrocyte destruction and profound anemia.

Autoimmunity in the cat

Several spontaneous autoimmune diseases have been described in the cat, including hyperthyroidism, hemolytic anemia, thrombocytopenic purpura, pemphigus vulgaris, pemphigus foliaceus, systemic lupus erythematosus, myasthenia gravis and arthritis.

Feline hyperthyroidism is recognized as an important clinical entity in older cats. The presence of autoantibodies against thyroid microsomes has been demonstrated by immunofluorescence in about one-third of these cases, while lymphoid infiltration is found in another third. Autoimmune hemolytic anemia, while usually occurring spontaneously, may also develop secondary to FeLV infection. An autoimmune thrombocytopenia has also been reported to be associated with FeLV infection.

Immunodeficiencies in the cat

Primary immunodeficiencies are rarely recorded in the cat. Thymic hypoplasia and lymphopenia have been reported in a Siberian tiger, while 'nude' cats – thymic aplasia and hypotrichosis – have been recorded in a litter of kittens. These kittens had no thymus, and showed lymphocyte depletion in T cell areas of the lymph nodes, spleen and Peyer's patches. Their most common congenital defect in immune function is the Chédiak–Higashi syndrome. This is classically seen in some Persian cats. Affected animals show defects in pigmentation with a characteristic pale coat color and red tapetal light reflection. Their leukocytes contain enlarged lysosomal granules but increased susceptibility to infections has not been observed. Of considerably greater importance as a cause of feline disease is failure of passive transfer of colostral immunoglobulins. This results in the development of severe and intractable bacterial infections in newborn kittens. The most important cause of secondary immunodeficiency in the cat is FeLV infection. Despite its name, this virus usually causes severe immunodeficiency in infected animals. Kittens born to FeLV-infected queens may show thymic atrophy and depressed allograft responses, while infected adult cats may develop a panleukopenia. As a result, they die due to fulminating bacterial infections. Many cats with chronic bacterial or fungal infections such as pneumonias, abscesses and stomatitis are found to be FeLV infected. Feline panleukopenia, due to a parvovirus, also causes an acquired immunodeficiency syndrome with severe leukopenia and lethal secondary infections.

Feline immunodeficiency virus

Feline immunodeficiency virus (FIV) is a widespread lentivirus that infects domestic and wild cats. Infection with this virus results in progressive depletion of CD4⁺ T lymphocytes. The resulting disease in many respects resembles human acquired immune deficiency syndrome (AIDS) and is an important model of the human disease. FIV replicates preferentially in feline T lymphoblastoid cells and causes a characteristic cytopathic effect *in vitro*. The virus receptor is probably not mediated through fCD4 (which is expressed on only a subset of T cells) but through fCD9. Infection is also associated with a marked, polyclonal expansion of B cells and of a subset of fCD8⁺ cells. As a result the CD4:CD8 ratio can be reduced to as low as 1.6, compared with a normal ratio of 3.3. Kittens artificially infected with

FIV initially exhibit few clinical signs, most notably anemia, lymphopenia, neutropenia and lymphadenopathy. Eventually a terminal AIDS-like illness develops. Natural FIV infections result in death as a result of secondary infections of the oral cavity, upper respiratory tract, gastrointestinal tract, skin or urinary system. Neurologic signs have also been described. Epidemiologic analysis suggests that FIV is mainly transmitted between cats by biting.

Gammopathies

Plasmacytomas, although uncommon, are well recognized in the cat. The great majority of these tumors secrete immunoglobulins of the IgG isotype, but IgA- and IgM-secreting myelomas have also been described. In some cases these plasmacytomas may be associated with the deposition of immunoglobulin-associated amyloidosis.

FETAL CALF SERUM

Hinnak Northoff, Abteilung Transfusionsmedizin, Eberhard-Karls-Universität, Tübingen, Germany

Willy A Flegel, Abteilung Transfusionsmedizin, Universität Ulm, Ulm, Germany

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Historical background

The beginning of cell culture techniques during the first decade of this century was marked by the finding that biologically derived fluids are required to maintain cells *in vitro*. Various supplements were used successfully, varying widely from tissue extracts, spinal and amniotic fluids, lymph and milk to plasma and serum. Later, substantial improvement was brought about by basal nutritive solutions (media) containing defined concentrations of salts, amino acids, sugars and vitamins, which, however, required supplementation by biologicals. The use of supplemented basal media is still a mainstay in cell culture techniques.

Rationale for use of fetal bovine serum

Serum is most commonly used as a cell culture supplement because it is readily available and relatively stable in composition. As most sera of adult animals contain naturally occurring heterophilic antibodies, sera free of relevant antibodies are desirable. In this context, the serum of unborn calves (FCS, fetal calf serum; FBS, fetal bovine serum) is advantageous because it is naturally devoid of maternal antibodies if collected properly. In cattle, there is no transplacental transfer of antibodies, which are transferred enterally in large amounts via the colostrum (low levels of antibodies of fetal origin, like antiviral antibodies, are often present in fetal calf serum). If free of antibodies, newborn calf serum is like fetal calf serum. In many culture systems, e.g. cultured human cells, homologous serum compatible for relevant blood group antibodies can be used with equal or better success than fetal calf serum.

Production process

Growing demand for fetal calf serum has fostered commercial preparation and supply. Today, use of commercial products is the rule. Processed fetal calf serum is also available (removal of lipids, γ -globulins, steroid hormones or low molecular weight components by dialysis, etc.).

Preparation

There is no firm, standardized procedure for preparation.

Suppliers usually buy the raw material from brokers; it stems mainly from large cattle ranches in the Americas, Australia, southern Africa or Europe. In the slaughterhouse, the blood of fetal calves is generally gathered by heart puncture. If collection is not performed under sterile, nonpyrogenic conditions, the contamination with bacterial pyrogens is frequent. Some manufacturers use closed, aseptic conditions and offer special products. Small pools of 4.5 l serum (from approximately ten calves) are shipped frozen to the manufacturers, who perform some quality control tests, homogenize sera into large pools of up to 2000 l and filtrate them before bottling. Depending on the pore size used (generally 0.1 μ m, sometimes 0.04 μ m), even mycoplasmas may be removed by this procedure.

Quality assurance

Codes for quality controls, including checks for viral contamination, exist only in some countries. As a result the quality may vary between different countries. The supplier will usually run a series of tests for quality control (Table 1). Many manufacturers currently use the Limulus assay for detection of pyrogens. This is, however, not necessarily sufficient to detect all biologically relevant endotoxins. Assays using monokine production (interleukin 1, tumor necrosis factor and interleukin 6) as indicator have been proposed for screening for functionally active endotoxins and proved to be superior to *in vivo* tests like the rabbit pyrogenicity test.

Generally, the users have to evaluate different batches of fetal calf serum to find the most suitable one for their special purpose. Preservation of cell culture characteristics, cell growth curve (lag period, doubling time, saturation density), plating efficiency and cloning efficiency are some frequently used criteria. Even within one batch of fetal calf serum,

Table 1 Quality controls for fetal calf serum

Content of
Proteins, glucose, fructose, minerals
Lack of contamination by
<i>Mycoplasma</i> , bacteria, endotoxins
Bovine viruses (e.g. bovine viral diarrhea virus, BVDV)
Antibodies, hemoglobin
Growth support of cell lines

differences of characteristics can occur if pooled sera were not homogenized completely before bottling.

Applications

Use in cell culture in cellular biology research and in the pharmaceutical industry is the major application for fetal calf serum. Culture supplement is usually 1–20% v/v fetal calf serum in the basal culture medium. Most users treat fetal calf serum for 30 min at 56°C in order to inactivate heat-labile complement components. Supplementation by fetal calf serum can provide cells with factors in physiologically balanced form (Table 2) which are necessary for cell survival, growth, differentiation and other cellular functions. On the other hand, potential cytotoxicity of serum should be considered because it is not the physiological fluid of the environment of most cells *in vivo*. The content of functionally active endotoxins (see above) can also have a critical influence, as this agent can modulate the growth and function of many cells either directly or by inducing cytokines. Contaminating bacterial substances can be antigenic and mitogenic.

Biohazards

Large pools of fetal calf serum may be contaminated with bovine pathogens, when one or a few calves car-

ried infectious agents. This may cause a biohazard if further processing cannot remove the pathogens, such as bovine viruses or possibly even the causative agent of bovine spongiform encephalopathy. It has been shown that bovine viruses are present in many commercial batches of fetal calf serum and may infect a variety of cell lines from several species. Obviously, bovine pathogens can be introduced into pharmaceuticals if fetal calf serum or derivatives thereof are used during the pharmaceutical production process.

Substitutes and future prospects

Much knowledge has been gathered on the relevant ingredients of biological cell culture supplements. Presently, there is no formula at hand which could generally replace poorly defined culture supplementation by biologicals like fetal calf serum. Hence, serum-free cell culture is still limited to defined culture conditions with adjustments to each cell population or cell line. The applications of serum-free culture techniques are certainly increasing and may eventually replace the use of fetal calf serum in many areas. These techniques provide a better control of culture conditions, can be free of pathogens and may reduce batch-to-batch variations to a minimum. This development will be accelerated by increasing sophistication of available formulas, which include mixtures of hormones, growth factors, transport proteins/albumin and attachment factors (hormonally defined media). Other substitutes such as conditioned media derived from cell culture supernatants and low protein or low serum media may themselves contain fetal calf serum or derivatives thereof.

Often fetal calf serum cannot be replaced owing to the lack of an adequate, convenient and economic alternative – despite its high costs. Fetal calf serum is therefore likely to remain a ubiquitous agent in laboratory-scale biology and immunology, as well as in industrial-scale biotechnology, for many years.

Table 2 Fetal calf serum factors relevant to cell culture

Biologically active substances
Cytokines, hormones (e.g. insulin), vitamins
Growth factors released during coagulation (e.g. platelet-derived growth factor, PDGF; transforming growth factor β , TGF β)
Extracellular biomatrix proteins
Attachment factors, spreading factors
Adhesion glycoproteins (fibronectin)
Transport proteins
Binding proteins (e.g. transferrin)
Lipids complexed to a carrier (albumin, lipoproteins)
Protection factors
pH buffer
Protease inhibitors
Radical scavengers (glutathione)
Viscosity of protein solution
Trace elements
Fe ²⁺ , Zn ²⁺ , Cu ²⁺ , Mn ²⁺ , Co ²⁺
Nutrients
Peptides, polyamines, lipids, sugars
Sporadic exogenous contaminants
Bacterial substances, viruses
Cellular products induced by exogenous materials
Interleukins from macrophages and lymphocytes
Proteolytic enzymes from granulocytes

FETUS AS ALLOGRAFT

Peter M Johnson, Department of Immunology, University of Liverpool, Liverpool, UK

Modern considerations of the haplo-nonidentical fetus as an allograft in outbred pregnancy have developed from initial postulates, put forward by Medawar, Brent and Billingham in 1953, that were derived from their work on transplantation tolerance. In these, they proposed that 1) the conceptus may not be immunogenic, 2) pregnancy may alter the immune response, 3) the uterus may be an immunologically privileged site, and 4) the placenta may be an effective immunological barrier between mother and fetus. They were also influenced by the earlier work in 1945 of RD Owen, who demonstrated transplantation tolerance between dizygotic twin cattle (who share a common placenta and blood supply).

In 1958, Woodruff showed that pregnant female rats could react immunologically against fetal tissue removed from one embryo and grafted to the thigh muscle, whereas the remaining intrauterine embryos were unaffected. This demonstrated that the 'transplantation privilege' normally offered to the fetoplacental unit in pregnancy depends on intrauterine mechanisms. However, several later studies in experimental animals have shown that tissue transplants (e.g. skin grafts) placed at intrauterine sites in hormonally primed or pregnant recipients are not exempt from immune rejection, although a degree of prolongation of graft survival times can occasionally occur. Thus, the pregnant uterus is not an immunologically privileged site. In addition, it is clear that pregnancies will normally survive in maternal hosts that have high levels of pre-existing alloimmunity from either natural immunization (previous pregnancy or blood transfusion) or experimental immunization with fetal or paternal cells.

The modern focus of attention on the fetus as an allograft has now been directed more toward the specialized features of fetal trophoblastic cells that appear to confer transplantation protection allowing

viviparous reproduction. Trophoblast is the first cell type to differentiate following fertilization and forms the lining cell of the placenta and extraembryonic membranes encasing the conceptus; it represents the entire fetal tissue interface with maternal blood and decidualized endometrial tissue. In humans, the outermost trophoblastic layer of the chorionic villous placenta is syncytiotrophoblast, a continuous cell layer without intercellular junctions, that has a mononuclear cytotrophoblast layer immediately below within the villous structure. It is through syncytiotrophoblast that the fetus 'eats, breathes and survives', and molecular expression by this cell reflects its wide variety of essential biological functions. There is a separate population of invasive extravillous mononuclear cytotrophoblast that migrate into the decidualized endometrium and also proliferate laterally to form the chorionic membrane; in early pregnancy, these extravillous cytotrophoblast cells display many of the cell biological characteristics of tumor cells in their proliferative and invasive properties, which largely cease after the first trimester of pregnancy. This entry will concentrate largely on human pregnancy, since there are numerous anatomic differences in placentation between species, but will also refer to observations in other species when appropriate.

Passive resistance of trophoblast to cytotoxicity

It is now clear that fetal trophoblast utilizes several mechanisms which may critically protect it from maternal cytotoxic attack. First, human placental villous cytotrophoblast and syncytiotrophoblast do not express any classical polymorphic class I or II major histocompatibility complex (MHC) antigens (e.g. HLA-A, -B, -DQ or -DR), and it appears that constitutive HLA expression may not be induced by any of the known exogenous upregulators (e.g.

interferon γ , IFN γ). Classical MHC antigens are thus not expressed throughout gestation, from the trophoectoderm of the preimplantation blastocyst to the syncytiotrophoblast of the term placenta. The genetic mechanisms of gene expression and control in syncytiotrophoblast, a true cellular syncytium, are difficult to envisage. However, there would appear to be little doubt that the lack of expression of classical class I MHC molecules at this site in humans is of central importance in protecting the fetal tissue interface from cytotoxic attack by maternal T cells or allo-antibody. There may also be other, more subtle implications, since syncytiotrophoblast can express endogenous retroviral particles; these are likely to be involved with syncytial cell formation, but could also strongly influence expression of other genes. In rodent pregnancies, in contrast, there is evidence of placental expression of some classical class I MHC antigens; the immunobiological implications of this are still far from clear.

Recent studies have shown comprehensively that the extravillous cytotrophoblast population in humans selectively expresses the nonclassical class I MHC antigen, HLA-G, which has limited genetic polymorphism; the HLA-G gene lacks an intact interferon-stimulated response element (ISRE) for upregulation. To date, HLA-G expression has not been noted in adult tissues and this class I MHC locus may have evolved for a specialized immunogenetic function in pregnancy. HLA-G protein expression in fetal tissues other than trophoblast remains controversial, notably in fetal thymus, where positive selection of HLA-G-restricted T cells could possibly occur. There has been speculation that HLA-G might serve in cytotrophoblast invasion and proliferation in endometrial tissue, or as a passive cell surface class I MHC molecule protecting this cytotrophoblast population from MHC-nonrestricted natural killer (NK) cell attack (see below) without presenting a classical class I MHC antigen that could act as a target for MHC-restricted T cell cytotoxicity. An opposing argument is that trophoblastic HLA-G expression may be a redundant evolutionary relic. This could be supported by observations that β_2 -microglobulin-deficient mice, obtained by homologous recombination in germ-line genes and which do not express constitutive class I MHC molecules, are capable of reproducing readily and with normal litter size; however, these mice lack functional CD8⁺ cytotoxic T cells and would not have the ability to distinguish self from nonself.

The final mechanism that trophoblast employs throughout gestation to protect itself from maternal cytotoxicity is to express a high level of complement regulatory proteins on its surface, notably membrane

cofactor protein (MCP: CD46), decay accelerating factor (DAF: CD55) and membrane attack complex inhibitory factor (CD59). The former is of particular interest since, for many years, a polymorphic cell surface antigen system termed trophoblast-leukocyte common (or cross-reactive) antigen (TLX antigen) attracted attention from reproductive immunologists as a potentially immunoregulatory cell surface polymorphic antigen expressed by both fetal trophoblast and maternal immunocompetent cells. It is now recognized that this TLX antigen is identical to CD46; its strong expression by all trophoblast subpopulations serves to protect this cell type from complement-mediated damage consequent to either maternal antibody attack or local tissue restructuring and hemostatic alterations that may promote persistent low-level local complement activation.

Active maternal immunoregulatory responses

A central creed in reproductive immunology is that there is active maternal immune recognition of pregnancy (i.e. of fetal trophoblast) that leads to cellular, antibody or cytokine responses which protect the fetal allograft. Taking antibody responses first, there has been much evidence that so-called blocking antibodies (which impair *in vitro* lymphocyte response assays) can be found in normal pregnancy sera and placental eluates. However, the data often are not convincing that these systemic effects can always be ascribed to specific antibody, rather than other serum factors, and that they occur in all successful pregnancies. For example, agammaglobulinemic women do not suffer undue problems of pregnancy failure other than indirectly following their susceptibility to infection. It is probable that the blocking antibody phenomenon is an effect rather than a cause of the immunologic success of outbred pregnancy.

Of more interest may be local cellular adaptations within the maternal endometrium and placental bed site. It is now recognized that mature CD3-positive T cells and, particularly B cells are comparatively rare at these sites. The predominant cell types are: 1) activated class II MHC antigen-positive macrophages (which serve as an immediate defense to infection at these vital tissue sites in pregnancy, but may also be providing nonspecific immunosuppressive mediators such as PGE₂); and 2) CD3⁺ CD16⁺ CD56^{bright} granulated lymphocytes (endometrial granulated lymphocytes, eGL). These latter cells have attracted much attention regarding their apparent novel phenotype and function. They may be hormonally regulated in that they occur in endometrial

tissue in significant numbers during the secretory rather than proliferative phase of the cycle, and are normally lost by menstruation. In pregnancy, their numbers increase still further in first-trimester endometrium (or, in ectopic pregnancies, in any decidualized tissue), but most CD3⁺ eGL have been lost by term. What is their function? Their phenotype most closely resembles that of NK cells and pre-NK cells, although most CD3⁺ eGL may not proliferate rapidly in response to interleukin 2 (IL-2) and do not express other NK cell molecules (e.g. CD16 or CD57). One postulate is that they are a form of NK cell in arrested maturation, perhaps because of persistent expression of HLA-G on the target invasive cytotrophoblast?

In this context, it could be relevant that several rodent models of recurring fetal loss in pregnancy appear to operate via a final mechanism involving attack by NK cells of macrophage-derived products against the fetoplacental unit. Unfortunately, clear immunopathological evidence for cellular immune damage at the fetal tissue interface in cases of human recurrent spontaneous abortion has been difficult to obtain. In susceptible rodent immunogenetic breeding combinations, several other potent immunomodulators can cause fetal loss (e.g. lipopolysaccharide treatment). Hence, examples of pregnancy failure in rodents may reflect endogenous genetic factors together with exogenous pathogens, endotoxins, or environmental stimuli. Nevertheless, scid/beige double mutant mice (that lack T cell, B cell and NK cell function) reproduce normally, although these mice do still bear a granulated lymphoid cell type in endometrial tissue. In the absence of environmental factors, an intact immune system may not be necessary for reproductive success.

More recent attention has been directed toward cytokine cross-talk that may occur at the fetomaternal tissue interface in pregnancy. One hypothesis has been that fetal trophoblast antigens (e.g. HLA-G) or other products might stimulate maternal lymphocytes in endometrial tissue to produce cytokines and growth factors that act in a paracrine manner beneficial to trophoblast growth and differentiation (the so-called immunotrophism hypothesis). Although the relatively low numbers of mature T cells in endometrial tissues could limit this effect, it is also well established that decidualized endometrial tissue extracts are particularly potent in demonstrating immunosuppressive effects. It is now clear that other cell types in this tissue are highly active in cytokine secretion (e.g. eGL and glandular epithelial cells). For example, there is evidence for the significant production of the colony stimulating factors (CSFs), tumor necrosis factor α (TNF α), IL-6 and trans-

forming growth factor β (TGF β) within decidual tissue. Similarly, fetal syncytiotrophoblast would appear to be excessively endowed with growth factor receptors, including those for the CSFs, IFN γ , TNF α , TGF β , epidermal growth factor and transferrin. Thus, a complex interactive cytokine network may be operative within uteroplacental tissue that provides both immunosuppressive and growth-promoting signals.

Based on the above considerations, it had been proposed that certain cases of unexplained recurrent spontaneous abortion in humans could result from a failure of active maternal immune adaptation to the fetal allograft in pregnancy and might be assisted by deliberate prior immunization with paternal or third-party cells to promote these missing protective responses. However, the most recent information now suggests that there is no strong conceptual framework for this hypothesis acting at a systemic level, and that alloimmunization in such cases may not always significantly improve subsequent successful pregnancy outcome rates in fully controlled clinical efficacy studies.

Fetal protection from prenatally transferred maternal IgG antibody

In man and certain other species, maternal immunoglobulin G (IgG) is selectively transferred prenatally into the fetal circulation following initial recognition by specific transporting Fc γ receptors on placental syncytiotrophoblast. This provides transient passive immunity to assist postnatal immune protection following parturition and release from the sterile intrauterine environment into pathogen-rich environments at a time prior to development of neonatal immunocompetence. Significant maternal IgG transfer occurs in humans from around the 20th–22nd week of gestation. However, together with beneficial antimicrobial immunity, deleterious maternal autoantibodies and fetal-specific alloantibodies could also potentially be transferred into fetal circulation. Hence, elegant mechanisms have evolved to protect the fetus from adverse maternal IgG antibody, notably maternal anti-HLA alloantibody (which may have developed from a previous pregnancy) and that would be expected to have catastrophic effects on the developing fetal immune system if allowed to penetrate further than extraembryonic tissue.

It is now recognized that maternal HLA-specific alloantibody with specificity for the fetal HLA type will be efficiently bound by nontrophoblastic cells bearing fetal HLA antigens (i.e. macrophages, fibroblasts, endothelium) within the villous mesenchyme of placental tissue, and will not reach the fetal circu-

lation. Similarly, any other maternal antibody to a fetal antigen expressed within placental tissues will be sequestered by binding to an antigen-expressing cell or by binding as a soluble immune complex to high avidity Fc γ receptor-bearing macrophages and fetal stem vessel endothelium that are abundant in these extraembryonic tissues; the latter have specificity solely for complexed rather than monomeric IgG. Hence, these potentially deleterious maternal antibodies are trapped by the placental 'sink' or 'sponge'. Indeed, many immunohistological studies have drawn attention to the extensive IgG and complement deposition within term placental villous tissues – essentially, the placenta needs only to survive this immunopathologic onslaught for up to 5 months, unlike other body organs.

The exceptions that escape placental trapping of adverse maternal IgG antibodies are also of interest. For example, maternal IgG rhesus (D)-specific or platelet-specific antibodies will meet their cognate antigen first on fetal erythrocytes or platelets, respectively, within placental stem vessels. Hence, erythrolysis or thrombocytopenia will occur *prior* to trapping of immune complexes on fetal Fc γ receptor-positive placental vessel endothelium. In addition, maternal organ-specific autoantibodies reactive with autoantigens not represented within the placenta will not be sequestered and retained at this site. Thus, for example, maternal IgG thyroid-specific autoantibodies can reach the fetal thyroid and can sometimes directly cause transient symptoms of autoimmune thyroid disease during the neonatal period of persistence of passively transferred maternal IgG autoantibody.

Conclusions

Our understanding of the immunobiology of the fetal allograft has progressed considerably over the past 40 years. Current attention in human pregnancy is focused on the probable specialized role of selective HLA-G expression at the fetal tissue interface and on elucidating the function of the numerous maternal

CD3-negative granulated lymphocytes that can be found in the surrounding decidualized endometrial tissue, together with the complex cytokine networks that may exist within these tissues. It is possible that all of the components and mechanisms contributing to the success of the fetal allograft in immunocompetent pregnant hosts have now been identified, even if not all of the details are yet known. However, it is impossible to test this hypothesis in humans, and difficult to test in experimental animals. Hence, further novel approaches to unraveling the immunobiological strategies employed for successful viviparity can be expected.

FEVER

Robert B Ashman, Department of Pathology, University of Western Australia, Nedlands, Australia

Since the writings of Hippocrates, fever has been almost universally recognized as a manifestation of disease. A linkage between the two was formally established by the demonstration that filtrates of

autogenous pus could cause fever when inoculated into rats; however, at the time this observation was made, the pyrogenic activity of bacterial endotoxins was unsuspected. The existence of an endogenous

pyrogen was definitively established in 1953, when Bennett and Beeson showed that leukocytes contain a factor that induces fever in the absence of infection. Subsequently, a moiety with activity similar to that of the leukocyte pyrogen was found in the serum of animals that developed fevers after inoculation of various microbial agents. The bacterial and endogenous pyrogens were not identical, as the former disappeared rapidly from the circulation, whereas titers of endogenous pyrogen increased, and showed a good correlation with the course of the ensuing fever. The induction of fever in conjunction with hypersensitivity responses, and the passive transfer of a fever-inducing substance in the serum of sensitized animals, clearly confirmed the endogenous origin of the pyrogen. Other organisms, such as gram-positive bacteria and viruses, can also induce fevers, the kinetics of which differ in some respects from those induced by bacterial endotoxin.

Endogenous pyrogens

Leukocytes, and macrophages in particular, produce a variety of cytokines that often exhibit similar or overlapping biological activities. Many of these have been shown to induce fever either directly or by the induction of other endogenous pyrogens. Although the use of recombinant material has clarified the specific functions and pyrogenic activities of the various species, their interrelationships are very complex, as they can induce their own – and each other's – production both *in vitro* and *in vivo*. The mechanisms that regulate these interactions have not been unraveled, but may involve inhibitory effects of prostaglandins on the synthesis of endogenous pyrogens. The major pyrogenic cytokines are briefly described below.

Interleukin 1

Although several cytokines have now been shown to induce fever *in vivo*, interleukin 1 (IL-1) is most likely to represent the molecule(s) originally described as the endogenous pyrogen. Two genes have been identified that code for two different forms of IL-1: IL-1 α and IL-1 β . Although the two forms of IL-1 exhibit only limited homology (<27%), both are translated as 31 kDa precursor peptides. These peptides lack a cleavage sequence, implying that an enzymatic step is required for processing of the precursor molecule to its mature form. Consequently, a proportion of the translated protein remains associated with the cell as the high molecular weight precursor. The biological activities of IL-1 α and IL-1 β are for the most part identical, implying that the short regions of sequence homology represent active sites common

to both forms. Analysis of recombinant IL-1 molecules has shown that both a 24.5 kDa and a 17.3 kDa peptide evoke monophasic fevers when injected into rabbits; however, the smaller peptide is approximately 100 times more active than the larger. This is consistent with the concept that a large, relatively inactive precursor is processed to a smaller, biologically active form. However, there may be more than one active moiety, as a 4 kDa peptide has also been shown to cause fever.

Tumor necrosis factor

Tumor necrosis factor (TNF) is a macrophage product that produces a classical endogenous pyrogen fever in rabbits and mice. Its biological activity is similar to that of IL-1, in that 50–200 ng kg⁻¹ of either factor induces comparable febrile responses. However, injection of larger quantities evokes a second peak, and there is evidence that TNF induces IL-1 both *in vitro* and *in vivo*. Another cytokine, lymphotoxin, shows considerable homology with TNF, and this substance also induces IL-1, and produces fever in animals.

Interferons

Interferons (IFNs) were originally described as antiviral agents, but they have been found to possess a wide range of biological activities, including pyrogenicity. However, substantially more recombinant human (rh) IFN α than rhTNF or rhIL-1 is required to induce a fever in rabbits, although this difference can perhaps be attributed to the species specificity exhibited by the interferons. IFN β and IFN γ are both pyrogenic for humans, though somewhat less so than IFN α . IFN α and IFN β show considerable amino acid homology, but IFN γ is quite distinct, and the mechanism of fever induction by the latter may also be different.

Interleukin 2

Interleukin 2 (IL-2) is known to cause fever in humans. Its half-life in the peripheral circulation is very brief, so it probably acts by stimulating the production or release of other endogenous pyrogens or pyrogenic prostaglandins.

Macrophage inflammatory protein 1 (MIP-1)

This cytokine has been cloned and sequenced, and is composed of two distinct but highly homologous proteins, the separate functions of which have not yet been characterized. MIP-1 is secreted in response to endotoxin, elicits localized inflammatory responses, is chemotactic for human neutrophils, and activates these cells for an oxidative burst. It also

induces a monophasic fever of rapid onset, approximately equal in magnitude to that induced by rhTNF or rhIL-1. However, the fever induced by MIP-1 is not blocked by cyclo-oxygenase inhibitors, so it is apparently initiated by a pathway that does not involve synthesis of prostaglandins.

Mechanism of fever induction
